The regeneration of cyanide solutions which contain sulphocyanide and ferrocyanide does not occur by electrolysis with direct current, whether the conditions of electrolysis be made oxidizing or reducing by varying the relative current densities at the anode and the cathode.

Dr. Kern's paper elicited considerable discussion, in which Messrs. G. H. Clevenger, F. C. Frary, F. A. Liddy, J. W. Richards, and E. P. Schoch participated.

Professor Schoch thought well of the fundamental idea of the Clancy patents.

Professor Clevenger gave an interesting account of his experience in a Butters cyanide mill. They had tried everything in the way of "insoluble" anodes, but passive iron. They found that peroxidized lead anodes had a life of about a year. He thought that the use of passive iron was an interesting and good suggestion. In the whole Professor Clevenger agreed with the conclusions of Dr. Kern's paper, though he thought they were based in part on insufficient evidence.

Dr. Richards described a mercury cathode cell of the Castner type with which he had made some laboratory experiments. It is a double-compartment cell, the two compartments being separated from each other by a baffle in the center of the cell. This baffle dips into the layer of mercury provided on the bottom of both compartments. The anode compartment contains a solution of caustic soda, sodium being deposited onto the mercury and the sodium amalgam being transferred to the other (the cathode) compartment. The latter contains gold sodium cyanide solution. Gold is deposited

and the cyanide solution is regenerated from the amalgam.

Mr. Lidbury remarked there would be an accumulation of caustic, but this would be an asset. Mr. Clevenger spoke of a similar scheme which was to be tried on a large scale, but as far as he knew nothing had come of it. He thought the scheme was not impossible.

Session in Boulder

The second technical session, held on Wednesday morning in the University of Colorado, in Boulder, was taken up by the reading and discussion of two papers. The paper by Clevenger and Hall on electrolysis of cyanide solutions was presented by Professor Clevenger; the paper by Lyon and Keeney on possible applications of the electric furnace to Western metallurgy was presented by Mr. Lyon. Both papers elicited a very animated and extended discussion, lasting in each case for almost an hour. As matter of fact, the discussion would have been continued further, if the announcement had not to be made that in spite of the heated discussion the lunch was getting cold.

Electrolysis of Aqueous Solutions of the Simple Alkaline Cyanides

The paper on this subject by Professor G. Howell Clevenger, of Leland Stanford University, and Mr. Mortimer L. Hall, of La Touche, Alaska, gives the results of an experimental investigation in which chemically pure potassium cyanide was used throughout. For details of the various series of experiments the reader must be referred to the full paper which also contains interesting notes on methods of analysis for the electrolyzed solution and a summary of the reactions (in part hypothetical) occurring during and after electrolysis.

The authors' conclusions are as follows:

The bulk of the decomposition of cyanide occurring during electrolysis is due to oxygen liberated at the anode through the decomposition of water.

The principal final reaction in solutions of cyanide containing protective alkalinity, which in cyanide mill practice is usually due to lime, is the formation of the corresponding alkali carbonate. This accounts for the formation of large amounts of calcium carbonate during the electrolytic precipitation of gold and silver from cyanide solutions.

A consideration of the reaction previously discussed will explain the failure in many cases to obtain regeneration of cyanide when such regeneration is theoretically possible. It is apparent that the decomposition of cyanide may easily be equal to or greater than that regenerated through the precipitation of the metal in solution.

The Liebig titration for the estimation of cyanide in an electrolyzed solution gives results which are low.

The changes taking place in fresh and electrolyzed cyanide solutions, upon standing, are different.

While not wishing to discourage investigators working along the lines of aiding extraction with refractory ores by electrolysis, we think that it is of importance to call attention to the disadvantages which may arise through the indiscriminate use of electrolysis with an ore pulp. First, a large loss of cyanide may result from which there is no benefit derived, and, second, electrolysis may actually interfere with extraction through the formation of a coating of calcium carbonate upon the ore particles.

The discussion was opened by Mr. Lidbury who in commenting on Professor Clevenger's paper and on Professor Kern's paper of the day before, thought that not enough attention was paid to a fundamentally important principle, often emphasized by Professor Bancroft, namely, that all electrolytic processes should be considered first of all as chemical reactions. We should endeavor to disclose the pure chemistry of the reaction. What is electrolysis called upon to do? What are the chemical conditions and the chemical reactions which we desire to produce? What are the anode reaction and the cathode reaction, if strictly separated and investigated separately? The investigation should be conducted

with exact observance of conditions, such as steady temperature, steady potential drop, etc. The evolved gases should be investigated, etc.

Professor Clevenger replied that his investigation had been purposely carried out just in the same way as the work under discussion had been done by the various practical experimenters all over the country. Temperature cannot be maintained constant in commercial mill practice. But he agreed that Mr. Lidbury was right about the way that future investigations must be carried out.

Professor Richards said that practical cyanide men were well acquainted with many of the chief chemical problems of their work, like the action of different solvents, etc. One chief difficulty of the application of electrolysis to cyanide solutions was found in the fact that for the electrolytic deposition of the gold only 2 per cent of the current was usefully employed, and 98 per cent was wasted and great care had to be taken to make this 98 per cent of current harmless so as not to destroy the cyanide. As to the life of lead peroxide anodes in cyanide solutions he said that if lead anodes were first coated with peroxide in an alkaline solution they would be found far more resistant than if oxidized in an acid solution.

Professor Frary questioned some of the hypothetical reactions in the paper.

Professor Schoch emphasized the wonderful opportunities in bringing in a meeting like this the practical and the so-called theoretical men together. As to the necessity of separating the anodic from the cathodic reaction, this was most important in the first teaching of electrolysis, though many widely used text books were shocking in overlooking this fact. Mr. Lidbury's criticism should make professors using such text books blush.

Mr. Skirrow thought that in a careful investigation conditions of temperature, current density, etc., should be varied one at a time. It was clearly impossible to study everything at once.

Possible Applications of the Electric Furnace to Western Metallurgy

The paper on this subject, by Dorsey A. Lyon and Robert M. Keeney, of the U. S. Bureau of Mines, first gives a review of the present status of the electric furnace in *smelting iron ores*. The fact that coke is unsatisfactory as a reducing agent in the electric iron ore reduction furnace (chiefly on account of the much better electric conductivity of coke as compared with charcoal) seems to limit the electric iron reduction furnace to the use of charcoal. Hence it is necessary that such a furnace be located in close proximity to a well timbered region, where charcoal as well as electric power can be produced at a low cost. This is unfortunate, especially as regards the situation in southern California and in other of our western States, where there are quite large iron deposits of A-No. 1 ore, but where coke is too expensive to permit of ordinary blast furnace smelting, and where the use of charcoal for electric furnace work is entirely out of the question, as there are no forests to furnish the wood necessary for its production. On the other hand, crude oil is generally more or less plentiful and comparatively cheap in such districts, especially in California.

As a result of a preliminary investigation conducted by the metallurgical section of the U. S. Bureau of Mines on the possibility of using crude oil as a reducing agent, it seems as if about the only manner in which crude oil may be used for this purpose is to first convert it into a fixed gas and then introduce this into the crucible of an electric furnace, thus preheating the gas to such a temperature that it will effectively reduce the iron oxides as it passes up through the shaft of the furnace.

A review is given of the commercial development of electric iron smelting in Scandinavia and California. From the Scandinavian reports it is shown how step by step the results have been improved. The output has been increased from 3.10

to 3.20 tons of iron per h. p. year. The electrode consumption has been reduced to 3 k. g. (6.6 lb.) per ton of pig iron. The cost and time required for repairs were items which could not be estimated beforehand. Experience has shown that both the cost and the time required are less than could have been hoped for. Wherever employment for the gas can be found, this should also be taken into account, as is being done at Hagfors, where its value for firing the open-hearth furnaces is estimated to reduce the cost of the pig iron by about 66 cents.

With respect to *copper smelting* in the electric furnace, reference is made to the same authors' recent Am. Inst. Min. Eng. paper on this subject (see our September issue, p. 522).

The smelting of straight *lead ores* in the electric furnace has never been attempted either commercially or on a large experimental scale, largely because of the ease and cheapness of smelting by combustion processes. For the smelting of ordinary lead ores it has no special application, but in the treatment of complex lead-zinc-silver ores the electric furnace, might be profitably used. The roasted ore could be treated in an electric furnace operated at a temperature such that the lead reduced by carbon melts and collects the precious metal values and the zinc is volatilized and condensed.

The use of the electric furnace in the metallurgy of non-ferrous metals has had greater application for the treatment of *zinc ores* than in the metallurgy of any other of the non-ferrous metals except aluminium and ferro-alloy manufacture. Since 1885, when an electric furnace for the treatment of zinc ores was patented by the Cowles Bros., experimental work has been conducted on the subject. The commercial application of the process, however, has not resulted to any great extent because of the difficulty of condensing the zinc vapor produced under the smelting conditions of the electric furnace. The cause of this difficulty has not yet been definitely determined. With few exceptions the experimental work has not been conducted on a very large scale, and so it may be said that the electric smelting of zinc ores is still in the experimental stage.

Undoubtedly the electric furnace has a very promising field in the metallurgy of zinc, but before its wide application can be expected the condensation problem must be solved and mechanical problems in connection with the electric furnace worked out. The latter should not be difficult. The special field for electric furnace work in zinc metallurgy is due largely to the low thermal efficiency of the present zinc retort which is given by Richards as only 7 per cent.

With the efficiency of the electric furnace varying from 50 to 75 per cent, the difference in the heat necessary for carrying out the smelting operations is so great as to permit of a higher cost of electrical energy than is permissible in many electrometallurgical operations.

The authors review the present methods of zinc smelting and compare therewith the electric furnace method of zinc smelting. They summarize the results obtained in commercial operation at Trollhättan, describe the experiments made by A. Stansfield and W. R. Ingalls at McGill University, refer to the experimental work of W. McA. Johnson, discuss the electric smelting of zinc sulphide ores with iron as desulphurizing agent, and then sum up the present status of electric zinc smelting as follows:

"The process is still largely in the experimental stage. There is no plant operating on a commercial scale except the Trollhättan works, taking from 7500 to 10,000 kilowatts. The experimental work mentioned is still going on, but as yet none of it has developed into a commercial operation.

"From what has been said concerning the work at Trollhättan and the results of others, it is very evident, as previously explained, that the difficulty lies almost entirely in condensation of the zinc vapor to a metal rather than blue powder under the peculiar conditions of the electric furnace. The electric furnace, mechanically or electrically, presents no great difficulties to solve, because all the troubles formerly experienced have been solved in the construction of large pig iron, steel, carbide

and ferro-alloy furnaces. The problem, then, is one of a metallurgical nature, and is caused by the different conditions and greater speed of smelting in the electric furnace than in the combustion retort.

"The opponents of the electric smelting of zinc ores, who as a rule appear to have no knowledge of the great development of the electric furnace itself in the treatment of other ores, often state that, while the retort is the weak part of the old system, so is the electrode the weak point of the electric method. Admitting that the retort is the weak part of the retort method, and judging from large scale electrometallurgical work on other ores, we do not believe that in general the electrode is an exceptionally weak part of electric smelting. The electrode problem, no longer a serious one, has been solved in iron smelting. It is only fair to assume that the designer of an electric zinc furnace should stand upon the accumulated knowledge and take the results of others when the metallurgical problems of electric zinc smelting have been solved. One editorial writer in the *Engineering and Mining Journal* of December 14, 1912, goes so far as to say, in reference to retorts and electrodes, 'nobody can say which will be the weaker.'

"While it is not the purpose of the writers to enter into a discussion of the relative advantage of processes, it may be of interest to present a few comparative facts regarding retort and electrode consumption.

"Ingalls' states that the average life of a Silesian retort over a period of ten years is 38 days. One charge is smelted per day. An editorial in the *Engineering and Mining Journal* of December 14, 1912, states that the Silesian retort takes 200 pounds of ore per charge. Hence a retort treats 7,600 pounds or 3.8 tons of ore. Ingalls' also states that a condenser lasts from 8 to 12 days, so that about four condensers are necessary for the ore smelted by a single retort. He also states that a seasoned retort is valued at 50 cents, and a condenser at 4 cents. Thus the cost of a retort and condensers for smelting 3.8 tons of ore is 66 cents, or 17 cents per ton of ore smelted.

"At Trollhättan, Sweden, the electrode consumption has been reduced to 6 pounds (3 kg.) per ton of pig iron produced. Considering that two tons of ore were charged for each ton of pig iron produced, the consumption per ton of ore is 3 pounds. The smelting conditions in electric iron reduction would not tend to be as strongly reducing as in the zinc retort, although the ore in each case would be an oxide. Hence it may be expected that the total consumption of electrodes in a large, properly designed zinc furnace would not exceed 3 pounds per ton of ore.

"There is no longer loss of electrode because of unconsumed ends, as this loss has been entirely overcome by joining both amorphous carbon electrodes and graphitized electrodes. This reduces the loss by one-half.

"In some experiments by the writers on a mixture of sulphide and oxidized copper ores, with no carbon in the charge, and the charge proportioned so as to contain 15 per cent sulphur, the electrode consumption with air blown into the furnace for partial pyritic smelting was only 2 pounds per ton of ore. However, the furnace was designed so that the charge protected the electrode from the air.

"Amorphous carbon electrodes can be obtained at from 3 to 4 cents per pound, so that, on a basis of a consumption of 3 pounds per ton of ore, the electrode cost would be from 9 to 12 cents as compared with a retort cost of 17 cents. These figures seem to show that, rather than 'nobody can say which will be the weaker,' the retort at the present time is the weaker.

"If the failure of the electric furnace in smelting zinc ores is not due to the electric furnace or the electrodes, what then is the metallurgical condition which causes condensation difficulties and has retarded the commercial application of the process? The difficulty is, of course, due to a difference in the smelting conditions of the electric furnace as compared with the retort. Both physical and chemical conditions influence the formation of blue powder. Some powder forms under certain

*W. R. Ingalls, *The Metallurgy of Zinc*, p. 545 and p. 242.

conditions of pressure and temperature. As to just what these conditions are has not yet been solved. It is a problem for the physical chemist.

"The chemical conditions leading to the formation of blue powder are due largely to the speed of reduction of zinc oxide in the electric furnace and to the presence of volatile impurities in the charge. Boudouard found that the permissible percentage of carbon dioxide in the zinc retort was very low, and that when the limit is exceeded the carbon oxidizes the zinc, causing formation of blue powder. The vapor of the zinc retort is usually below this limit or not much above it, so that the zinc is condensed chiefly as liquid zinc. But in the electric furnace the temperature directly beneath the electrode in either the arc or resistance furnace is so high that the reduction proceeds so rapidly that the large amount of carbon dioxide formed does not have a chance to be reduced to monoxide by the hot coal of the charge before entering the condenser. Hence there is the oxidation of the zinc mentioned.

"By the use of electrodes of large cross-section it is probable that this concentrated heating could be reduced so that, rather than a very high temperature at one place, there would be a uniform comparatively low temperature all over the charge. This was found to be the case in the smelting of iron ores, both at Héroult, California, and Trollhättan. Or the current could possibly be distributed more evenly by flat electrodes of rectangular cross-section.

"The formation of blue powder is also caused by volatilization of silicon, which condenses on the zinc either as silicon or silica. For example, in some experiments at the Bureau of Mines Laboratory the condensed fumes from a ferro-silicon furnace contained 67.69 per cent SiO_2 , 9.72 per cent Al_2O_3 , 4.11 per cent FeO , 0.20 per cent MgO , 1.90 per cent CaO , with the rest carbon. This volatilization of silicon occurs in any electric furnace operated with an arc, as in ferro-silicon manufacture, when there is silica in the charge. At the lower temperature of a resistance furnace it is not so likely to occur.

"The solution of this problem is very probable, and, while it is difficult, there is no reason why it should not be worked out in time. When this is solved, and it is not necessary to resmelt a large proportion of blue powder as at Trollhättan, where two tons of blue powder are smelted for each ton of ore treated, it is probable that electric zinc smelting will proceed rapidly. The use of iron as a desulphurizing agent does not seem to have advanced as far as reduction of the oxide with carbon, and it is probable that the latter will keep its present supremacy. Some work has been done in an electric furnace operated under pressure or vacuum, but only a beginning has been made in this direction."

As to the treatment of *complex sulphide ores*, the authors speak as follows: The electric furnace has a possible field in Western metallurgy at places where there are complex sulphide ores of lead, zinc, copper, gold and silver. With the solution of the zinc condensation problem it is not unreasonable to suppose that the ores of this class can be electrically smelted so as to get a fair recovery of the metals and at least the precious metal values. Also, owing to the fact that practically as high a temperature as desired may be obtained in the electric furnace, it would be possible to smelt complex ores which have high gold and silver values, but which are too low in base metals, such as lead and zinc, to make their recovery worth the additional expense of concentration.

In the blast furnace 10 per cent of zinc in the charge causes sticky slags, and with a much higher percentage the operation of the furnace is very irregular and difficult. These slags could be fused readily in the electric furnace. In such a case, if the ores contained copper and zinc, the ore could be charged into an electric blast furnace using matte as a collecting agent for the gold and silver.

In the smelting of *gold-silver ores* carrying no lead or copper, to form either a lead bullion or a copper matte, but containing iron sulphide, the electric furnace might be used in connection with an air blast for oxidation of the iron sulphide, and an iron matte as a collecting agent for the gold and silver. The value

of iron matte as a collecting agent is still largely a matter of personal opinion, but from the pyritic smelting which has been done with iron as a collecting agent, and from some experiments of the writers, using iron matte in the electric furnace, it is evident that a fair recovery can be made in this way. As in the case of electric copper smelting, the electric furnace treatment of these ores is still in the speculative stage.

Mines in isolated districts, where fuel is usually high and where the power operating the mine or mill is often hydro-electric power, could in many cases melt their cyanide precipitates more economically in electric furnaces than in combustion furnaces (as is done in Chihuahua, Mexico). The construction of a small Siemens type of furnace is simple and inexpensive. By operating the electric furnace when one of the units of the mill was down for repairs, or on the mine shift when little hoisting or drilling was being done, no additional electric installation would be necessary. This simply means that power which under ordinary conditions is wasted would thus be utilized.

On the treatment of *chromium, tungsten, molybdenum, and vanadium concentrates*, the authors speak as follows: The treatment of these ores is of particular interest to the Western metallurgist, for all of these ores are mined in the Western States, but their treatment has been confined to concentration by ore dressing or chemical methods, or shipment of their concentrates to the ferro-alloy manufacturer or the metal refiners. If these concentrates could be treated locally they would be given a "form value" at once, and thus enable the district in which they are produced to retain money which is now expended for freight charges, and also to retain the profits of the ferro-alloy manufacturer, which, because of the specialty of the product, are rather large.

For this work relatively high temperatures are required, so that the operation could not be performed metallurgically or economically in a blast furnace, reverberatory furnace or crucible. Tungsten is reduced from the trioxide at a temperature of 1300°C ., and vanadium from the vanadate of iron or calcium at about the same temperature. The melting point of tungsten is 2800°C ., molybdenum 2000°C ., and vanadium 1750°C . All of these temperatures are high compared with that for the reactions usually performed in combustion furnaces. Of course, the melting point of the ferro-alloy would not be as high as that of the pure metal, and becomes lower with increased percentage of iron. The electric furnace is especially fitted for the smelting of rare metal ores to produce ferro-alloys because of the ease with which high temperatures were maintained.

The present status of the manufacture of *ferro-alloys* in the electric furnace is briefly considered, together with the reasons why the growth of this industry has been more slow in America than in Europe. The general construction of electric ferro-alloy furnaces is discussed as follows:

In general, an electric furnace for ferro-alloy manufacture consists of a crucible without a roof, having either a conducting or a non-conducting hearth and an upper vertical carbon electrode or electrodes. Most of the furnaces first built had a conducting hearth, and this practice is still common in furnaces up to 750 kilowatts capacity, but for larger sizes experience has shown the non-conducting hearth type to be preferable. One reason for this is because there is considerable loss of electric energy by dissipation through the lining, and hence there is a tendency to have a lower power factor. In working a small furnace intermittently, i. e., discharging completely before charging again, the conducting hearth furnace is much easier to operate and start cold. When a large furnace is to be operated for several months continuously on one alloy, this advantage of the conducting hearth is of no importance. A factor which has been little considered in the construction of ferro-alloy furnaces is the power factor, as they are generally completely enclosed in sheet steel, when hands would do as well, with much less induction resulting in the circuit.

The ferrosilicon furnaces are lined with carbon, while the furnaces to be used in producing other alloys are generally

lined with a basic lining of magnesite or dolomite brick or a mixture of tar with either material. When low carbon ferrochrome is being made the lining is sometimes chromite. Generally a furnace is designed so that the electrode or electrodes are at a sufficient distance from the sides to permit a chilling of the material charged upon the walls. This has been found to give the most satisfactory lining. Under such conditions furnaces have been operated for two or three years without being relined. The average furnace operated continuously runs about two years before being shut down for repairs. A furnace operated intermittently must, of course, be relined more often.

Owing to the greater part of the reduction of oxides in ferro-alloy manufacture being done at high temperature by solid carbon, most of the furnaces are run with an open top, into which the charge is placed around the electrode. Under these circumstances there is a considerable waste of heat which might be used in preheating the charge. In these furnaces the electrode usually dips about 12 to 15 inches beneath the top of the furnace, which is kept filled with cold material so as not to expose the molten mass beneath. There is burning of carbon monoxide around the electrode, and an escape of a large volume of gas through the top of the furnace house. It is stated that one of the Alby type of carbide furnaces is operating with a closed top at Kopporaen, Norway. The Helfenstein furnace does away with the open top also, as it is air tight, and in addition has feeding shafts where the charge is preheated by the waste gases. In the manufacture of the higher-priced alloys, such as ferrotungsten, it is impossible to use any furnace but one with an open top, because of the intermittent nature of the operation, but in making ferrosilicon and ferrochrome it seems advisable to preheat the charge as much as possible and prevent as much oxidation of the electrodes as is possible in this manner.

A large number of the first ferro-alloy furnaces were supplied with direct current when the furnace house was built adjoining the power house, so that there was only about 20 feet between the furnace and the generator. It was soon found that the electrolytic action in a direct-current furnace resulted in deposition of potassium, sodium, calcium, aluminium with the alloy so that as pure a product could not be obtained with direct as with alternating current. When alternating current was first used, single-phase current was the more common in general application, so that the arrangement remained the same as previously, the generator delivering directly to the furnace at the desired voltage without any transformation.

Later, when three-phase current became prevalent, furnaces designed to take single-phase current were connected in groups to three-phase systems by several methods. Then the single phase furnaces were replaced for large scale work by the present-day three-phase furnace.

The cost of electric power for electric furnace is finally considered and figures are given for the production of electric power with gas engines and steam turbines.

"As to what the cost of power produced by gas engines would be, a reliable engineering concern has furnished data which show that, with coal at \$3.00 per ton, which it is assumed will contain 13,000 b.t.u. per pound, electric power can be produced at about the following cost when using gas-engine-driven generators at a load factor of 75 per cent:

Size of Plant, Kilowatts	Cost of Power in Cents per Kilowatt Hour.	
	Coal at \$3.00	
2,000	0.745	
4,000	0.687	
6,000	0.649	
8,000	0.637	
10,000	0.633	

"These figures include operating costs and fixed charges

"The same engineering concern has also supplied the writers with data in regard to the cost of electric power produced by steam-turbine-driven generators. Based upon this data, the cost of electric power is shown in the following table, with coal at \$3.00 per ton. These costs include operating costs and fixed

charges, and, as before, it is assumed that the coal has a heating value of 13,000 b.t.u. per pound and that the load factor is 75 per cent."

Size of Plant, Kilowatts	Cost of Power in Cents per Kilowatt Hour,	
	Coal at \$3.00	
2,000	0.688	
4,000	0.597	
6,000	0.532	
8,000	0.526	
10,000	0.514	

A table is finally given of the approximate cost of power at various electrochemical plants in various countries. The prices range all the way from \$5 per kilowatt year (Rjukan, Norway, for nitrate manufacture) to \$110 per year (Baintree, England, for electric steel making).

The paper elicited a spirited discussion.

In a communicated discussion by Mr. F. A. J. Fitzgerald, the scope of the work of the U. S. Bureau of Mines was criticized.

Mr. Lyon, in reply, stated that the work of the Bureau was to ascertain facts and make the public acquainted with the facts. He welcomed constructive criticism of the work of the Bureau of Mines by the American Electrochemical Society. A committee specially appointed for this purpose could render useful service.

Professor Richards stated, unofficially, that Director Holmes was desirous of having such a committee appointed in order that his Bureau might work in full harmony with the national societies in investigating questions of national concern in the various fields of science coming within the purview of the Bureau. Professor Richards moved "that the Board of Directors be requested to appoint a conference committee authorized to confer with the Director of the Bureau of Mines regarding the activity of the Bureau in electrochemical and electrometallurgical matters."

Mr. F. A. Lidbury seconded this motion, which was then unanimously carried.

Dr. Richards, in discussing the paper, said that electric zinc smelting was no longer on the experimental scale. There was a new plant now in operation at Helsingfors, in Finland. At present 2500 h. p. are used, but the plant is to be enlarged to 6000 h. p. But the United States is behind Europe in this development. As to the idea of some electric zinc men that electric zinc smelting was chiefly an engineering problem, this was quite erroneous; the chemical and metallurgical problems must remain in the foreground.

Mr. C. A. Hansen discussed, at some length the possibilities of electrochemical methods in the West. He also emphasized the excellent prospect of electric steel casting plants. He gave a set of very interesting figures, favorable to the electric furnace, in comparison with the acid open-hearth, the Tropenas converter, and the crucible. As these figures, based on the experience of several years in large-scale operation, were given by Mr. Hansen from memory, we reserve their publication for a future issue, when the figures will have been verified by Mr. Hansen and given out authoritatively.

Dr. John A. Matthews, of the Halcob Steel Co., said that while in Scandinavia and California the electric iron ore reduction furnace had made rapid and important progress, yet in the Eastern States of this country the possibilities of the electric furnace in the iron and steel industry were chiefly in three directions: first, for the production of high-grade steel; second, in combination with the Bessemer converter for large tonnage products; third, for steel castings. This third field was probably very important.

Mr. E. L. Crosby of the Detroit Edison Company spoke of possibilities of electric furnace loads for central stations.

Mr. L. B. Skinner emphasized the comparatively high cost of electric power in the West. In Denver no power could be had at such a price as 1 cent per kw. hour. This fact had to be considered in connection with electrochemical schemes in the West. Further, the cost of labor is high. He referred to an extended trip of a distinguished Western metallurgist to Europe

to study the status of electric zinc smelting there not so long ago; he had not found that the problem had been solved commercially.

Owing to the lateness of the hour the discussion had to be interrupted. It was, however, taken up again the next day in connection with the two electric zinc papers.

Session in Golden

The third technical session was held in the School of Mines at Golden in the afternoon of Thursday and was probably the best attended session, there being nearly too members and guests present.

Mr. McGregor presented his paper on electrostatic concentration and Dr. Lind his paper on the transformation of radiant into chemical energy. The two electric zinc papers, one by Mr. Johnson, the other by Mr. Petersen, were next presented and discussed at considerable length. On account of the lateness of the hour all the other papers were then read by title and briefly discussed.

Progress in Electrostatic Ore Dressing

The paper by Mr. Frank S. MacGregor on this subject attributes the continued success of the electrostatic concentration process (Huff process) to three factors:

(1) Use of electricity produced by commercial electro-magnetic generators and transformers, whose output and potential is steady and capable of easy regulation in the place of the

characteristic which enables the separation just described to be made, but, if the crystal be immersed for a short time in a very weak solution of copper sulphate, it becomes coated with a film of copper sulphide. This is an excellent conductor of electricity (speaking electrostatically) and if the particle is dried at a moderate heat, it behaves as a conductor, and is repelled by the electric charge in the same manner as pyrite, chalcopyrite, graphite or other conducting minerals. Separations of zinc sulphide from gangue have been made in this way on a laboratory scale for some time, but the method has been utilized commercially for the first time in the Ouray plant.

The treatment is very simple: the zinc product is run into tanks, covered with a 0.5 per cent solution of copper sulphate, allowed to stand for a short time, the solution then drawn off for further use, the ore then dried and on passing through the electrostatic separators a 40 per cent zinc product is raised to 51 per cent with only 5 per cent zinc remaining in the gangue product, making a recovery of 97 per cent. The consumption of copper sulphate is very small, a new solution treating several lots.

Besides the zinc field other fields are now being entered by electrostatic concentration. Excellent work in the concentration of crude silver ores has been done in a 30-ton mill in Austin, Nevada.

In Australia a Huff plant concentrates molybdenite from its gangue.

Two graphite mills now employ this method for removing the mica from the graphite flake, the solution of a very vexing problem. It is not improbable that the entire concentration of some graphite will be done electrostatically.

A recent development of great importance, both to the process and to the industry it affects, if the present indications are borne out, is for the cleaning of coal, both anthracite and bituminous. With anthracite occurs slate and other impurities which in the finer sizes are very difficult of separation. Electrostatic separation has offered a solution for this problem, reducing the ash in the "culm" from 25 to 30 per cent to 10 or 12 per cent.

In bituminous coal, the problem consists in the removal of ash and sulphur. Sometimes most of the sulphur present is "organic," so associated with the carbon that it cannot be mechanically removed, but when the sulphur is present as "pyrite" or in "bone," it is readily repelled, and with its extraction comes a large reduction of the ash. Activities are just entering this field.

A typical mill flow sheet for an electrostatic plant consists of a cylindrical dryer, about 4 ft. x 20 ft., made of sheet iron; bucket elevator to the top of the mill, carrying the dried ore to the screens. In some cases only a "scrap" screen is needed if the sizing required is 20 to 50 and through 50 mesh. If the various minerals will break mechanically free above 20 mesh, one or two coarse screens are necessary, as 6 to 12, 12 to 20 mesh. Then the ore is taken to the separators, through which it falls by gravity, the conductors and non-conductors as separated passing directly to storage bins. Returning a small amount of middlings from each separator back into the system is beneficial in increasing the tonnage and making cleaner products. These middlings finally pass out of the system in the finished products.

The power required is small, a 3-hp generating outfit being sufficient to electrify a plant of from one to fifty separa-

ON TOP OF PIKE'S PEAK

very erratic frictional static machines which were formerly tried.

(2) Use of concentrated and powerful electrostatic field by means of two adjacent electrodes, giving steadiness and strength to the action.

(3) Use of a grounded machine constructed almost entirely of metal, and therefore free from electrical disturbances.

A review is given of the use of this process and the results obtained at the following plants: U. S. Smelting, Refining & Mining Co., at Midvale, Utah; Calumet and Sonora Mining Co., at Cananea, Mexico; Sunnyside Mines in Eureka, Colorado; Mary Murphy Mine at St. Elmo, Colorado, and a custom zinc plant at Ouray, Col.

Zinc smelters pay a much better price for a high-grade zinc concentrate than for a lower one, even if the impurity is only gangue, and it is not always feasible to remove all this gangue on the ordinary wet tables without entailing too great a loss of zinc. At the latter plant an interesting electrochemical action has been utilized to raise the percentage of zinc in the zinc product.

Ordinarily a crystal of zinc sulphide is a non-conductor, a

tors. The machinery of one plant is operated by 12 actual hp, which includes power for the dryer, elevator, screens and six separators. One attendant will care for a shift, exclusive of handling ore.

In conclusion the author said that while the installation of electrostatic separators has not been as rapid as the exploitation of some other metallurgical processes, it has developed a unique field of its own, to which no other process is as well adapted, and the tonnage treated electrostatically is steadily increasing.

The paper was discussed by Mr. G. E. Collins, who gave interesting details of the result obtained with electrostatic concentration at one of his mines and compared it with electromagnetic concentration.

The Transformation of Radiant Into Chemical Energy.

A paper by Dr. S. C. Lind, of the Bureau of Mines, gave a summary of a continuation of his theoretical and experimental researches in this field. The results are summed up as follows:

Much experimental evidence is now at hand in support of the principle of electrochemical equivalence in gas reactions taking place under external ionizing agencies.

The use of the term "applicability of Faraday's law to gas reactions" may lead to confusion, especially in the case of reactions produced by electrical discharge, in which the measured current does not correspond directly to the quantity of chemical change. The term ionic-chemical equivalence in gas reactions seems preferable.

The theoretical maximum amount of ozone producible per hour by one gram of radium in equilibrium is estimated to be about 0.72 gm. Warburg's premises by means of which he estimated a lower value are discussed and the sources of error pointed out.

A method is shown by which the coefficient of the transformation of (ionizing) radiant energy into chemical energy may be calculated from the N/M ratio (where N is the actual number of pairs of ions produced and M the number of molecules entering into reaction).

For several *endothermic* reactions the transformation factor is shown to have the low average value of about 2 per cent, the same as has been found for some reactions produced under other forms of radiant energy.

The ratio of chemical to radiant energy in *exothermic* reactions is of the same low order, indicating that the influence of the free chemical energy in these reactions when produced by ionizing agencies, is very subordinate in importance, if it exists at all.

The paper was discussed by Professors Frary and Schoell.

The Art of Electric Zinc Smelting

Mr. Woolsey McA. Johnson's papers on this subject begins with a frank statement that "strictly speaking, there is no art of electric zinc smelting, for the commercial trials in this country, Canada and abroad have been clever, but are not art, since none of them are pronounced commercial successes.

"Our ideas and practical embodiment thereof are radically different from previous commercial attempts. We are not, however, claiming anything more than our personal faith in our ability to operate our process on zinc-lead-copper ores, recovering spelter, base-lead bullion and copper matte in one operation at a probable handsome profit under certain conditions. It is evident that the only criterion of a successful new process is the actual production of finished product at a profit for the market under actual commercial conditions."

The author quotes from an old report of his own, made in 1904, that the weak points of the present method of treating zinc ores are high labor charge per ton of ore, high fuel cost per ton of ore, and low recovery from even high-grade ores with restrictions as to nature of ores, while the advantages of a commercial electric zinc furnace would be large units, higher thermal efficiency, ease of control over smelting and production of pure spelter from impure ores.

Mr. Johnson then points out some of the inherent difficulties

of the problem. "... This very friendship of electricity and zinc is seductive, for any experimenter with 20 kw at his disposal, a few firebrick, some zinc ore and a couple of carbon electrodes cannot help making some zinc, only a few pounds, to be sure, but enough to allure him to further pursuit. And the very contrariness of the metal that seems to have so much free-will is that if one tries to make 100 per cent of zinc vapor as commercial zinc-dust, one will fail. For zinc is a peculiar metal.

"All our attempts up to 1909 were concentrated on the condensation of zinc vapor to spelter. We were correct in the statement, I believe, that we knew seven or eight years ago that the main conditions for good condensation were as follows:

"1. A regular flow of pure gas.

"2. Space at right temperature.

"3. Sufficient time."

The author discusses the production of blue powder instead of liquid smelter and distinguishes between "chemical" and "physical" blue powder (see this journal, Vol. 10, p. 451) and says that there are a number of conditions which produce chemical blue powder and that all but three of them can be easily prevented by foresight, provided their causes are known. In one of the tables in the paper giving the results of some of his last year's work it is seen that on complex ores, high in FeO and analyzing 4 per cent S the author has exceeded the condensation factor of 50 to 70 per cent, obtained in retort practice on simple ores well roasted.

The author sums up the requirements of successful electric zinc smelting as follows:

1. A first-rate preheater, mechanically strong and machine operated. Preheating *per se* has no advantage save to reduce kw hours per ton of ore. Preheating must be done right, not too hot, not too fast, not too slow, and not too cold, with a progressive application of metallurgical means.

2. The flow of heat through the charge in the electric smelting furnace and slag must be under perfect control. The electricity must be controlled, and care must be taken that the zinc globules in eductor assume no statical charge, otherwise coalescence of the spherules is hindered.

3. A regular flow of pure zinc gas must be delivered at proper temperature to the condenser.

4. The condenser must be durable and under good metallurgical control.

When all these conditions are fulfilled, spelter will come as a result of continuous electric zinc smelting in surprising amounts.

"The present Johnson zinc smelting process depends commercially upon the by-products. Furthermore, there is no doubt that our recoveries of lead, copper, gold and silver will be much higher than those of a lead furnace or of a copper furnace.

"Our general proposal is to treat low-grade ores high in by-product values. While we have treated oxidized ores, as Joplin 70 per cent zinc or even oxide of zinc, at the plant of the Continuous Zinc Furnace Company, we prefer to use low-grade ores analyzing about 35 per cent zinc.

"It seems distinctly probable that the cost of treatment of the zinc ores in the Johnson electric zinc furnace will be roughly inversely proportional to the percentage of contained zinc. Our process, therefore, will have quite an influence on the concentration of zinc ores and utilization of crypto-crystalline ores which are now commercially unavailable. It is thought by us that the general tendency, when we are successful in our commercial trial, will be to shorter and more direct concentration with as much of the Cu, Zn and Pb in one concentration as is possible. Lead smelting and copper smelting with low rate for power will be as cheap or cheaper in the Johnson furnace than in the ordinary lead or copper furnace because of the increased recoveries, provided metals stay at average prices. The relation between concentration and smelting will be different. It looks as if what the Johnson process needs were zinc-iron middlings with considerable included

galena for maximum commercial efficiency, though, of course, existing concentration methods will also be applicable. We see that the general commercial conditions governing grade of ore are diametrically opposite in the Johnson process and in the retort process, where, with the exception of dry carbonate zinc ores, the cost of treatment increases as the grade of ore treated is lowered. Metallurgical needs of the Johnson process are for fluxing ores high in lime and iron."

"While I hesitate to disagree with Mr. Ingalls, who has studied so long on zinc problems, yet when he says that, 'if there be any dreams of an electric furnace analogous to a blast furnace in which run of mine ore may be charged roughly and from which spelter, lead and perhaps also copper matte may be obtained concurrently, I fear that there will be no realization of them.' I take issue direct with him. He, in my judgment, is not unqualifiedly wrong, but qualifiedly wrong. The success of our process will come at first because the Johnson furnace is similar and analogous to a lead blast furnace.

"The use of ZnO prepared by a fired process from low-grade sulphide ores in an electric furnace does not appear especially attractive, for we had the idea of igneous concentration of zinc ores making zinc oxide on apparatus similar to Wetherill grate in 1908 with subsequent electric smelting of ZnO so produced, but put aside the idea. However, the Truax process for manufacture of zinc oxides out of slags has, to my notion, certain brilliant possibilities and is a triumph of American originality. It certainly looks good. The Betts process, using silicon as a reducing agent, has decided possibilities. Consideration of wet or hydrometallurgical processes for zinc ores is useless. Their metallurgy is complicated, plant expensive, and cost of treatment high and uncertain. Quantitative analysis writ larger does not spell metallurgy. High recovery may some day bring them to life, but only at the time when every Italian laborer knows as much as a \$1000-a-month chemist. Their only chance, and that a remote one, is for very low-grade ores containing an insoluble gangue."

Mr. Johnson thinks that his particular problems are those of an engineer rather than those of an inventor and gives a number of tables of runs in his furnace during the last year. (Since the tables printed in the advance copies of the papers contained numerous numerical errors, the reader must be referred to the corrected tables which will appear in the *Transactions of the Society*.)

The "accounted zinc factor" in three runs (leaving aside a fourth run with a split condenser pipe) ranged from 80.5 to 81.9 per cent, the condensation factor from 77.8 to 81.5 per cent. The "accounted zinc factor" is defined as the ratio of weight of zinc accounted for in all products to weight of zinc delivered to electric furnace. The "condensation factor" is defined as the ratio of weight of zinc in spelter produced to the sum of weight of zinc in flue dust plus weight of zinc in ladle skimmings plus weight of zinc in blue powder plus weight of spelter.

In the same three runs the kilowatt hours per lb. spelter varied between 3.10 and 3.74, the kw. hours per short ton of preheated charge between 1452 and 1748, the thermal efficiency (estimated in two ways) between 33.8 and 41.4 per cent, the total electrode carbon consumption per 1000 kw. hours between 5.57 and 8.25 pounds. The spelter made was sold to a brass founder in Hartford.

"Our aim in these tests, basically considered, was to attain a condensation factor higher than retort practice. I estimate the maximum average yearly condensation factor attained in retort plants in the United States at 65 per cent. Many retort plants in this country, however, have a condensation factor of less than 60 per cent. Of course, the mixture of ores used at our Hartford experimental plant is not metallurgically or commercially possible in retorting practice.

"At our Hartford plant we have mastered condensation on an experimental scale, for some of our best condensation has been with refractory ores."

"Mr. Ingalls, in his extremely clear article, speaking of the claims as regards power consumption, states: 'While it is doubtful whether such a result has yet been actually realized by anyone, the claim is plausible with respect to certain kinds of ores, although even then it is necessary to assume a high furnace efficiency. It would seem that 1200 kw. hours per 2000 pounds of ore would be a sufficiently brilliant realization. Even such a one would put electric zinc smelting upon a sound basis in so far as power consumption is concerned. It is curious to note that 1200 kw. hours given by Mr. Ingalls as lower probable limit is upper probable maximum limit of power consumption which I have set down for 35 per cent zinc ores. Actually we have bettered this figure, and 600 kw. hours for a 35 per cent zinc ore does not seem to be impossible.

"With a glance at the future, and basing our reasoning on our own progress in the past three years, and extrapolating this progress, the prediction is hazarded that electric zinc-lead smelting will have a treatment cost of as low as \$6.00 per ton of ore, and that the losses exclusive of roasting losses will be: Zinc 40 pounds, lead 1 pound, copper 2 pounds, silver 0.30 oz., gold 0.01 oz., per ton of ore. This is for the ultimate future. For the immediate future multiply this estimate by two and we have a safe estimate of what can be done."

Mr. Johnson's paper elicited quite an extended discussion. Dr. Richards emphasized as one of the principles of the Johnson process the preheating of the charge so as to remove water vapor and reduce the reducible oxides (iron) with the carbon without reducing the zinc. He also said that Mr. Johnson had paid special attention to the treatment of complex ores, such as are not treatable with the retort process, like Bully Hill ore. But it may be questioned whether it would not be better to begin with simplest ores.

Mr. E. J. Ericson criticized briefly some special points in Mr. Johnson's paper and asked whether the claim of a condensation factor as high as 80 per cent was not a misprint, since others, like DeLaval, had not succeeded in condensing any such percentage as this as liquid zinc. Dr. Roebor said that it was not a misprint, but that according to Mr. Johnson the condensation factor in his more recent work was 80 per cent or more. This was confirmed by Dr. Richards, who said that in the DeLaval furnace the zinc vapor was overheated, which caused condensation difficulties.

Mr. C. A. Hansen took up some points of the discussion of the day before. He thought the electric furnace was not suitable for all zinc problems. He also emphasized that the development of the electric furnace had been held back for several years by superficial statements of men who knew or should know better.

Mr. F. S. MacGregor discussed electrostatic separation in zinc metallurgy, with reference to the discussion, by Mr. Collins, of his own paper.

Mr. L. B. Skinner reviewed and criticized Mr. Johnson's paper at some length. He thought that the paper was incomplete and that the tables did not give sufficient data. He also emphasized that the development of a new process should be carried out in such a way that the simplest problems were first solved, beginning with chemically pure materials. He agreed with the author that hydrometallurgical processes were not promising for zinc.

This latter remark induced Mr. John L. Malm to speak briefly on his own process. A paper on this subject is expected to be presented at the next meeting of the Society.

After a few more remarks by Professor Clevenger and Professor Richards the discussion was closed and the second electric zinc paper, by Mr. Peterson, was taken up.

The Electric Zinc Furnace

The paper by Mr. Peter E. Peterson gives a quite detailed description of the experiments which the author has made during the last years in Butte, Montana. The author describes in detail, with illustrations, the construction of the various electric furnaces and condensers which he has used.

In this last experiments the efforts at improving the con-

condensers were temporarily abandoned and arrangements were made to recover all zinc products. To accomplish this a new furnace was built and special iron condensers were made to recover the blue powder; also a bag house was used to catch the zinc oxide in fumes.

A continuous twelve-day run was made without difficulties of any kind.

The charge was fed in every hour, and slag and matte tapped every twelve hours.

"This furnace in its present improved form is about all that can be expected of any furnace. There are far less difficulties encountered than in running an ordinary blast furnace. The deterioration of the furnace is small. Such a furnace should run from six months to a year without any extensive repairs. Large units can be constructed by merely the addition of more electrodes, and there is no reason why units of 25 to 50 tons each could not be operated as easily and cheaply as the one-ton units."

As to the metallurgy of electric zinc smelting Mr. Peterson says as follows:

"In the operation of the electric zinc furnace the composition and condition of the smelting charge is quite as important as the furnace. More care must be exercised in making up furnace charges than in ordinary blast furnace practice. The charge must be such that at all times there is a perfect reducing atmosphere in the furnace; the slag must be such that deterioration of the furnace lining is reduced to a minimum, and with a sufficiently high formation temperature to volatilize the zinc. A matte must be made that is uniform in composition and is readily tapped from the furnace, and made in sufficient quantity to effect a good saving of copper, gold and silver. The proportion and nature of the reducing carbon is important. As before mentioned, a perfect reducing atmosphere must be maintained, and at the same time the reducing carbon must be completely consumed. If an excess is added, it cannot be burned by an air blast as in blast-furnace practice, and the only oxygen available for its consumption is that held in combination by the constituents of the furnace charge.

"The physical character of the charge is quite as important as the chemical for the best work. The charge constituents should be finely divided so as to allow the various reacting elements to be in intimate contact with one another, thus insuring more perfect and economical results. But the charge must not be too fine when charging in loose rather than in brickette form. The particles should be of such weight or size as to readily settle from the zinc vapors and gases passing outward into the condensers. If the particles are too fine they are apt to find their way into the condensers in the unmetled condition.

"It is necessary to have the charge absolutely dry. The presence of water even in small quantities is serious, due to the oxidizing of the zinc vapor by decomposition of the water. What is still more serious is the instantaneous generation of steam and other gases, causing a great increase in the velocity of gases, thus disturbing the condensation of the zinc in the condensers and thereby causing a loss of zinc and also a loss of silver and other metals, due to furnace charge being blown outward into the condensers.

"If it is not possible to mix the charge with hot calcines from the roasting furnace and then immediately feed it to the electric furnace, there must be a preheating furnace to heat the charge before introducing it into the electric zinc furnace.

"The making of slags is governed by the nature of the furnace linings, and these are dependent on the nature of zinc concentrate or ore to be smelted. If the concentrates are high in iron and low in silica, then a basic slag high in iron is made, and consequently a basic furnace lining (such as magnesite brick) is used; and if the reverse is the case, then high-silica slags with silicious furnace linings are used.

"The principle used in the elimination of zinc from slags was to make slags of such high formation temperature as to prac-

tically volatilize most of the zinc before slagging of the charge begins.

"In silicious slags the high percentage of silica is the principal controlling factor. In basic slags the percentage of reducing carbon is increased, which for practical purposes gives the same effect.

"In the work I have been identified with we have had practically no difficulty in eliminating zinc from either basic or silicious slags. The degree of elimination depended on the quantity of power used. Following are analyses of slags showing how zinc elimination can be varied:

	Zinc	Copper	Iron	Insoluble	Silver	Gold
Slag No. 1..	0.3%	0.24%	16.1%	66.2%	1.2 oz.	trace
Slag No. 2..	1.6	0.13	19.2	57.5	0.6	trace
Slag No. 3..	5.5	0.47	22.9	45.5	4.1	0.01 oz.
Slag No. 4..	8.5	0.38	23.5	44.4	2.1	trace

"In the treatment of complex ores the other metals, gold, silver and copper, are also recovered. This is accomplished by producing a collector (matte) similar to the lead button in crucible fire assaying.

"In the earlier work it was attempted to use as a collector a matte consisting principally of iron sulphide, but its use was not attended by any degree of success. The matte formed was very irregular in composition, varying from metallic iron to iron sulphide. The amount of matte formed was also irregular, and it was found necessary to add copper ores until the furnace charge would assay in the neighborhood of 1 per cent copper in order to get a matte uniform in quantity and composition. The quantity of matte was varied by varying the percentage of sulphur in roasted zinc calcines. Zinc calcines were successfully treated that varied from 2 to 15 per cent sulphur. The best results were obtained between 5 and 7 per cent sulphur. One of the important reactions in this connection is:

"Coke was found to give the best results as reducing agent. When coals were used it was noticed that the condensing of the zinc was seriously interfered with, due to deposition of fine carbon or soot in the condensers from the decomposition of the hydrocarbons in the coal."

The author discusses briefly methods of treating blue powder to change it into liquid zinc, and the possibilities of the design of a more efficient condenser.

"Electric zinc furnaces constructed on the same principles of heating as retort zinc furnaces have given as good condensing results. In these furnaces the heating of the furnace charge is accomplished by the radiation of heat from an electric arc located above the charge. Practice has proven this a very inefficient means of electric heat, yet so far as condensing is concerned it gives the best results."

Mr. Peterson finally illustrates "a proposed condenser for electric furnaces that should have a large capacity and be effective in its operation. The principle of the condensing is to pass the gases from the electric furnace through a molten bath of zinc; the bath is automatically maintained at the right condensing temperature by being covered with a molten bath of zinc chloride which boils at a temperature which will not allow the molten zinc bath to get too hot. The passage leading to the molten zinc is heated to prevent any condensing and consequent clogging of the tubes.

"For the operation of this type of condenser the zinc vapors must be distilled under pressure; for observations made with this idea in mind there should not be any difficulty in maintaining a pressure of 2 pounds per square inch (0.13 kg. per sq. cm.), which should be sufficient to work this condenser.

"The quickest and most effective method of condensing any vapor to liquid is the one mentioned above. A good illustration of the method of condensing is the passing of steam into water."

An estimate, worked out on a one-ton unit, of the costs per ton of pay charge, is given as follows:

Roasting	\$1.00
Supt. and Assay Office, etc.....	1.00
Labor based on 33-ton plant.....	.83
Powder—1401 Kw. hours, at 0.332 cent.....	4.65
Depreciation of plant.....	.40
9.5 lbs. electrodes, at 14 cents.....	1.33
0.1215 ton coke screenings, at \$5 per ton.....	.60
440 lbs. matte. Cost of marketing.....	2.86

Total cost \$12.67

"With the electric zinc furnace the following extractions can be depended upon for the above costs: Zinc extraction, 85 per cent; copper extraction with 5 per cent copper in charge is over 95 per cent, and with 1.5 per cent copper in charge is over 84 per cent; silver extraction, 65 to 72 per cent; gold extraction, from 98 to 100 per cent.

"The gold, silver and copper are recovered in the form of a copper matte. The difference in the value of the metals and that actually obtained from them is called the cost of marketing the matte.

"The zinc as obtained with the process at its present perfection of condensation with the above costs contains only 30 per cent spelter ready for the market. The remaining 70 per cent of the zinc is obtained in the form of an 80 per cent zinc product, as blue powder and some zinc oxide. This zinc as produced by the electric zinc furnace would be worth \$4.36 a hundred pounds when spelter is selling at \$5.50 per hundred, that is, when the 30 per cent spelter produced is placed on the market and the remaining 70 per cent of the zinc in the form of an 80 per cent product is shipped to zinc smelters on an ore basis treatment charge. Greater economies could be effected if the electric smelter had retorts of its own to treat this high-grade concentrate of blue powder and zinc oxide.

"If a straight zinc concentrate assaying 50 per cent zinc is shipped to a zinc smelter, the probable basis of settlement would be as follows: 85 per cent of the zinc content at market price of spelter, with \$16 deducted for treatment charge. With spelter at 5.5 cents per pound, one ton of 50 per cent concentrate is worth \$30.75.

"The electric smelter, after deducting \$12.67 for treatment, would return for the same concentrate \$23.41. But if a complex zinc concentrate containing approximately 10 per cent iron with copper, gold and silver values were to be considered, the difference would be greatly in favor of electric smelting. The penalties on iron, etc., and the poor extraction of copper, gold and silver by the retort smelters would make it impossible for them to compete with the electric zinc smelter.

"In the West complex zinc ores are abundant, and in some cases water power can be obtained near the mines, which would be an added advantage to the electric smelter by effecting a saving to the miner on freight on concentrates.

"Another probable source of increased revenue would be the sale of zinc products, as zinc oxide, for the paint industry. Statistics show that, in 1910, 16 per cent of all zinc produced in the United States was sold as zinc oxide, and in this form brought 0.1 of a cent more per pound than if sold as spelter. There is absolutely no difficulty in making zinc oxide suitable for paint by the electric furnace. The principal accessory required is a bag house and packing plant. A small percentage of the product could be sold as blue powder at prices about equal to that of spelter."

Mr. Peterson's paper was briefly discussed by Mr. Clevenger, Mr. Skinner, Mr. Ericson, Mr. Snow, and Dr. Richards. Mr. W. M. Snow, of the Illinois Zinc Co., said that in improved modern retort practice metal recoveries of 86 to 91 per cent were obtained. While the condenser of present zinc metallurgical practice had been evolved by try-and-hit-and-miss methods, it was nevertheless quite an efficient instrument.

Dr. Richards pointed out the following difference in condensation in retort practice and in the continuous electric furnace. In the former the condition of the gases is continually changing, in the latter it is constant. This difference may

necessitate a very different design of an efficient condenser in both cases.

Electric Smelting of Chromium, Tungsten, Molybdenum and Vanadium Ores

The paper by Robert M. Keeney, of the Bureau of Mines, on the above subject first takes up the electric smelting of chromite and the production of ferrochrome.

The author discusses the reduction of chromite by carbon, silicon, aluminium, calcium carbide, further the available ores and raw materials and the process of manufacture.

The electric furnace used in the manufacture of ferrochrome may be one of several types, all of the principle of the Siemens crucible with a conducting hearth, or similar to the Héroult steel furnace, with vertical electrodes in series.

"The process of manufacture of ferrochrome consists of mixing a charge of chromite and anthracite coal in proportions based upon the theoretical calculations given. This is shoveled into the open top of the furnace around the electrodes. The furnace is charged at regular intervals so as to keep the top in a solid condition. The ore is very finely powdered, but the coal is about as it comes from the mine. There is some loss by ore being carried off with the gases which escape at the top of the furnace.

"The ferrochrome is tapped from the bottom, at intervals of from two to four hours, into iron pots set on cars, from which it and any slag are dumped when solid. The slag and metal come out of the same tap hole. When cold the metal is broken up with hammers to separate it from the slag and packed into kegs or boxes. For tapping an iron rod is used to open up the tap hole, which is plugged with fire clay.

"Ferrochrome manufacture is carried on continuously, in some cases for two years, before shutting down the furnace for repairs. In one operation, directly from ore, ferrochrome containing down to 5 per cent carbon can be made economically. It has been possible to produce an alloy containing as low as 2 per cent carbon in one operation, but great care is necessary in the regulation of the charge and the operation of the furnace. The slags from the average ferrochrome furnace making a 5 per cent carbon alloy run from 0.5 to 1.0 per cent Cr_2O_3 ."

The author then discusses the refining of ferrochrome. Decarburization of high-carbon ferrochrome is accomplished by melting the alloy with a slag of lime, chromite ore and a little fluorspar. Other methods of refining are briefly noted.

The author then describes some experiments made by him in 1912 on the production of ferrochrome from chromite with carbon as a reducing agent. The conclusions drawn are: "First, that ferrochrome can be easily manufactured directly from chromite in the electric furnace; second, that the percentage of carbon in the ferrochrome cannot be kept low by regulating the carbon charged without excessive loss of chromium in the slag; third, that the percentage of carbon in the ferrochrome must be regulated by decarburization with an oxide slag of iron or chromite after tapping off the slag from reduction; fourth, that silicon and phosphorus cannot be kept low in the alloy under the strong reducing conditions necessary; fifth, that sulphur can be easily slagged; sixth, that, as the addition of lime does not seem to aid in removing phosphorus, it is advisable to use no lime, but as pure raw materials as possible; and, seventh, that the power consumption should not exceed 3.7 kilowatt-hours per pound of ferrochrome tapped, or 0.85 kilowatt-year per ton. Some further notes on power and electrode consumption are added.

The author next takes up ferro-tungsten, giving historical notes, theoretical considerations of the reduction of wolframite, ferberite or scheelite with aluminium, silicon or carbon, and describes the process of manufacture as follows:

"Ferro-tungsten is manufactured from ores in three ways: First, by direct reduction with carbon in a crucible; second, by reduction in an electric furnace by some reducing agent other than carbon; and, third, by direct reduction with carbon in an electric furnace.

"In manufacturing ferrotungsten by the crucible process, concentrates are placed in a clay-lined crucible with the proper proportions of reducing agent and flux, and heated to a high temperature in a gas-fired furnace. There is considerable wear on the crucible in this method. For a 30 per cent tungsten alloy the crucible will last about three heats, but for a 65 to 75 per cent product they last but one heat. Higher percentage tungsten alloys than this are not made in the crucible furnace.

"In the electric furnace process, ferberite, wolframite, hubnerite or scheelite are reduced with carbon in an arc furnace. As with many expensive alloys, the process is generally an intermittent one, *i. e.*, the reduced charge is tapped from the furnace before another charge is added, or the charge is let solidify and chiseled out of the furnace. Sometimes a campaign of several days is made. The reduced alloy is either decarburized with refining slags in the same furnace or melted and refined later in another furnace. The furnaces used are similar in design to the ones described for ferrochrome production, but a more complete recovery is effected by the use of a tilting rather than a stationary furnace. Wolframite, ferberite and scheelite are reduced easily in the electric furnace, most of the manganese being volatilized. Scheelite is more difficult to reduce, and very sticky basic slags result. There is a greater loss in its reduction, so that it does not command as high a price as the other ores, selling for about \$1 per unit less. The product is tapped into molds, broken up on cooling, and packed into kegs or boxes."

The author describes some experiments made by him on the reduction of ferberite with carbon to produce ferrotungsten in the electric furnace. From the experiments the following conclusions are drawn: "First, ferrotungsten can be produced directly from ferberite in the electric furnace; second, by the use of a decarburizing slag before tapping, the percentage of carbon in the alloy can be kept below 2 per cent; third, manganese, silicon, phosphorus and sulphur do not enter the ferroalloy in high percentages; fourth, the loss of tungsten in the slag need not be excessive, and, fifth, the power consumption need not exceed 3.46 kilowatt hours per pound of ferrotungsten tapped, or 0.79 kilowatt year per ton."

In discussing **ferromolybdenum** the author gives again historical notes and theoretical considerations on the reduction of molybdenum ores. Concerning the process of manufacture the author says:

"The commercial manufacture of ferromolybdenum is carried on in an electric furnace of the electrode type operated as a resistance furnace, or in a crucible furnace of the resistance type. Comparatively little ferromolybdenum is made because of difficulty in getting ores. This is due to the fact that satisfactory methods of concentration for molybdenite ores have not been fully worked out as yet. . . .

"Buyers require an ore or concentrate containing 90 to 95 per cent molybdenite, for which the price is about \$450 per short ton.

"In commercial manufacture, raw or roasted molybdenite, iron turnings, lime and coke or coal are mixed to give a ferromolybdenum of desired proportions, and treated in the electric furnace. The furnaces are operated intermittently, *i. e.*, one charge is completely discharged before another is added. Ferromolybdenum is first made as a high-carbon alloy containing 3 to 4 per cent carbon. This is then decarburized with a lime slag or a slag of lime and iron oxide. If the latter is used the percentage of iron in the alloy is increased."

From some experimental work of the author on the electric smelting of molybdenite the following conclusions are drawn: "First, that ferromolybdenum low in carbon can be made directly from molybdenite in the electric furnace, with excess lime as a desulphurizing agent and carbon as a reducing agent; second, that a product of low percentage carbon can be made, and, third, that sulphur can be readily slagged as calcium sulphide with a charge of excess lime."

The paper is concluded by some notes on **ferrovanadium**.

"Most of the ferrovanadium made is produced by the thermit

process, by reduction of the oxide V_2O_5 in a crucible with carbon or by reduction of vanadate of iron with carbon in a crucible. In Europe some ferrovanadium is made by reduction of the oxide, sulphide or vanadate of iron with carbon in the electric furnace.

"The largest source of vanadium is the Peru deposit of patronite, a sulphide of vanadium containing about 60 per cent sulphur and 20 per cent vanadium. In Colorado and Utah there are large deposits of low-grade carnotite, a uranium and vanadium oxide mineral. Another ore found there is roscoelite, which contains vanadium oxide but no uranium.

"Patronite ore is first roasted and then reduced by the thermit process. Or, in the electric furnace it may be directly reduced with lime as a desulphurizing agent and carbon as a reducing agent. The other ores are treated by chemical or ore-dressing processes to obtain the vanadium as oxide or vanadate of iron, and then reduced with carbon in a combustion or electric furnace or by the thermit method. With oxide the electric furnace method is similar to the production of ferrotungsten with carbon as a reducing agent. The sulphide reduction is similar to that of molybdenite with lime and carbon. Several methods have been patented using silicon as a reducing agent in the electric furnace. The process as carried on in the electric furnace has no novel features beyond those stated regarding chromium, tungsten and molybdenum. Decarburization is with oxide of iron ore or oxide ore of vanadium. Vanadium is rather difficult to reduce, and as a result excess carbon is used, which is absorbed up to about 1 to 4 per cent."

The Carnotite Industry

A paper on this subject by Dr. Siegfried Fischer, Golden, Colo., is interesting in its relation to the production of radium.

Mineralogical investigations have shown two sources which contain uranium in sufficient amounts and of which there are large enough deposits to justify their commercial working. These are pitchblende and carnotite. While there are considerable deposits of monazite, the thorium mineral which also carries at times small amounts of uranium, its comparatively low radio activity eliminates it from becoming a true source for radium production.

Up to recent years pitchblende was the commercial uranium ore.

The author's paper discusses the possibilities of carnotite for winning radium. Carnotite is a dark green to canary yellow, soft, powdery impregnation in some gangue material such as sandstone, limestone or clay, and on rare occasions in coal. According to the percentage of uranium in an ore, the yellow color and the radio-activity are more or less dominant.

Data are given on the analysis of carnotite ores, and occurrence. The main sources of carnotite are Colorado and Utah. Up to recent years nearly all the carnotite was shipped to Europe. All the radium made was a foreign product, and it was thought that America was incapable of utilizing its own crude material. "This idea is now a thing of the past, as only last month \$30,000 worth of radium was shipped abroad by an American firm. It will probably not belong before this country is one of the main producers of this valuable element."

"The intrinsic value of carnotite lies in its uranium and vanadium contents, and on these factors the commercial value is based. It is rather hard to give definite figures which will hold true in all cases, as the signed contracts between the dealer and the buyer are of an extremely varied nature. The only data that I can vouch for are from a Colorado firm selling carnotite, and the figures held for last year.

"The contract stated that ores must contain at least 2 per cent U_3O_8 and a maximum of 5 per cent V_2O_5 if anything at all was paid for the vanadium. On this basis the U_3O_8 sold at \$1.25 per pound, and the vanadium oxide at \$0.30 per pound. For foreign shipments the cost per pound of V_2O_5 was \$0.70 *f. o. b.* Hamburg or Liverpool. The price for the uranium to these ports is not known to me. For each

FIGS. 1 TO 10.—TESTING PLANT, COLORADO SCHOOL OF MINES. (FOR DESCRIPTION SEE PAGES 500 AND 580.)

per cent over the percentage stated in the contract the price per pound increased \$0.05.

"The same firm claims that the profit per ton is \$20, and the net cost per ton of ore is between \$50 and \$60, including sampling and analyzing.

"This crude industry is very simple. The ore is mined and sampled, analysis is made at both ends, and the product is sold on contract. But more recent researches performed in this country will undoubtedly put the carnottite industry on a more scientific and commercial foundation."

The author discusses at some length the question whether concentration is desirable or not as a first step in the treatment of carnottite. European trade seems to demand that the material be delivered without mechanical change. But the author pleads in favor of concentration and gives as his argument an abstract of his article published in this journal, June, 1912 (our Vol. 10, page 356).

As to subsequent chemical treatment the author distinguishes three steps: Extraction of values; separation of uranium and vanadium; production of radium from uranium.

As to the extraction of values (see also the author's article in our issue of August, 1912, Vol. X, page 469) there are two treatment methods in use at present—acid and basic extraction.

With respect to *acid* extraction processes information is given on the Flech, Haldane, White patents 880,645 of March 3, 1908, and 890,584 of June 9, 1908.

"The acid process has never appealed to me for the reason

FIG. 4.—SCHEME OF BASIC TREATMENT OF CARNOTTITE

that so many impurities are brought into the extraction product, and must be gotten rid of at some stage of the operation. The patent also shows that the process is a tedious one, requiring many steps, thus increasing the time, reducing the output and increasing the cost. In spite of these facts, however, a plant is in operation based on these patents. Whether or not it is a success time alone can show, since it has been running less than a year."

A general diagram of the *basic* treatment scheme is shown in Fig. 4.

Most of the work along the line of the basic extraction of the values from carnottite was done by Warren F. Bleeker, now with the Standard Chemical Company of Pennsylvania. Bleeker's patents 1,049,330 (January 7, 1913), 1,015,469 (January 23, 1912), 1,050,796 (January 21, 1913), and Fischer's patent 1,054,102 (February 25, 1913) are outlined.

"Radium being closely allied to barium, a barium separation was performed on pitchblende ores. On this basis I have treated several uranium concentrates obtained from carnottite; and have had fairly good results. The quantity of concentrates used having been comparatively small, the barium and radium sulphate residues were not of sufficient amount to make absolute examinations on them, but the uranium residue, after treatment to eliminate all foreign matter, showed a decided decrease in radio-activity. Three methods are claimed to be applicable to carnottite for the extraction of the radium,

their commercial value depending greatly on the locality in which the manufacturing of the radium salts will take place. For further knowledge on this topic we will have to await the publications of the Bureau of Mines in Denver, which is doing extensive and most valuable work in this direction.

"As no industry can be considered a success until all the by-products are utilized, the carnottite industry cannot be classed as a fully developed commercial process. Vanadium has an established market; the demand for radium is increasing steadily, but what becomes of the uranium? When we consider 2,600,000 parts by weight of uranium will produce only one part of radium, it is evident how insignificant, commercially speaking, the amount of radium is in comparison to uranium. And yet for this important by-product of the carnottite industry there is practically no market demand. Some uranium is used in the glass and porcelain industry as a color medium, but the amount is a mere bagatelle. This subject calls decidedly for research. Some of the large steel companies have tried to use uranium in their line of work, but with little or no success. This seems to have discouraged investigators, and the work spent on this element, outside of producing radium, has nearly ceased. I would like to suggest investigating alloys of uranium with other metals besides iron. It may be that it will contribute properties to some that may be of the greatest value and open up a market for what is now practically a waste product."

Base-Metal Thermocouples

A paper by Prof. O. L. Kowalke, of the University of Wisconsin, discusses the possibility of getting reliable base-metal thermocouples.

One of the chief causes for the inaccuracy of a thermocouple is heterogeneity of the wires.

"Since the voltage generated by the couple for a given temperature is the summation of all the electromotive forces due to the contact of two dissimilar metal portions, it can readily be seen that it is imperative that the metal be as homogeneous as possible if the electromotive force indicated be that resulting from the two metals at the hot junction. If, then, the couple is composed of metal which is not homogeneous, then at each junction of two dissimilar metals there will be set up a voltage which is a function of the temperature existing at that point. Should the position of the couple be changed with respect to its depth of immersion, then the resulting voltage will be changed even though the temperature had not changed at all. A couple made of wires which are perfectly homogeneous is apt to be rather expensive, and the only combination which seems to fulfill this condition is the platinum and platinum-rhodium couple.

"It is possible to get a couple which is sufficiently homogeneous so that the indications are satisfactory for many commercial purposes where an accuracy of about 25 to 50 degrees is wanted. This condition is realized in the combinations of which base metal couples are made. Not all of the couples meet this condition with the same accuracy, and not all of the couples retain their original accuracy. Some couples appear to change or deteriorate with use more than others, due to oxidation, crystallization, segregation of the metal and other undetermined causes.

"It was the purpose of this investigation to determine how electromotive forces of couples varied with the temperature, and how constant this force remained with successive heatings and coolings, and also when exposed to various temperatures for extended periods of time.

"Couples were purchased from five of the prominent makers, and were cut to lengths of about 18 inches. To each couple about 3 feet of flexible lamp cord was soldered, and the wires at the point of soldering and all other required points were carefully insulated from each other."

These couples were subjected to the following careful tests: Calibration with a length of 4 inches heated; calibration with a length of 15 inches heated; heating to 400 deg. C. per 24 hours and renewed calibration with a length of 15 inches

Ore Dressing and Metallurgical Plant, Colorado School of Mines. Figs. 1 to 8 on page 587: Fig. 1, Outside View, Ore Dressing and Metallurgical Plant, Colo. School of Mines. Fig. 2, Preparation of Samples. Fig. 3, Classifier and Jigs. Fig. 4, Concentration Tables. Fig. 5, Wilfley Roaster. Fig. 6, Stamp Batteries and Plates. Fig. 7, Tube Mill and Cyanide Department. Fig. 8, Sampling Apparatus. Fig. 9, Elevator and Trommels.

heated; heating to 600 deg. C. for 24 hours and renewed calibration; heating to 800 deg. C. for 24 hours and renewed calibration.

The wires of the five couples had the following composition, the negative element being given first, the positive second:

- (1) Alloy of nickel and chromium, alloy of nickel and iron.
- (2) Nickel with a small amount of aluminium, iron-nickel alloy.
- (3) Nickel with a small amount of aluminium; iron with a small amount of nickel.
- (4) Nickel with a small amount of iron; iron with a small amount of nickel.
- (5) Nickel-copper alloy; iron-manganese alloy.

These couples had different protective coverings, of which one with a winding of asbestos cord, over which there was

applied a solution, presumably sodium silicate was apparently the most robust and satisfactory of the whole lot.

The results of the tests are given in form of diagrams and tables. They are thus summarized by the author:

"This series of investigations seem to point to the fact that it is possible to obtain a base-metal couple which is reasonably homogeneous and will give indications of temperature which are sufficiently constant to meet the needs of perhaps the greatest number of requirements for high-temperature measurements in the industries.

"There are some instances where the temperature is to be known to an accuracy better than 25 deg., and for such requirements it would be necessary to use a higher grade of equipment, and, furthermore, for such requirements it will be necessary to make frequent calibrations.

"It would seem reasonable that the makers of thermocouples determine from the purchaser the particular conditions under which the couple is to be used and that the calibration of this couple be made for the same length of immersion at which the purchaser is going to use it.

"A couple which will indicate an apparent difference of temperature amounting to about 130 deg. C. when immersed at different lengths in the bath or furnace is not giving the service that ought to be rendered.

"From these tests it appears that not all manufacturers are careful in sending out couples which have been thoroughly annealed to remove all strains resulting from mechanical treatment. Once the couple has attained its permanent structure there does not seem to be much change in the electromotive force."

Osmium-Platinum—A New Alloy

A brief paper by Dr. F. Zimmermann, of Baker & Co., Newark, N. J., gives an account of a research made to find a substitute for iridium-platinum on account of the growing scarcity of iridium.

Highly refined platinum and osmium have been successfully combined in widely varying proportions yielding alloys of commercial value. While the two metals may be combined in almost any proportion, alloys containing from 1 to 10 per cent of osmium and 99 to 90 per cent of platinum are chiefly used.

Great purity of the components is essential, as the presence of small percentages of other elements appears to be very detrimental to the properties of the resulting alloy. According to the chemical and physical behavior, it seems that one part of osmium in an alloy with platinum will take the place of two and one-half times its weight of iridium. The osmium-platinum alloy is very acid-resisting, and for this reason may be of great service in the electrochemical industry. Its electrical resistance is considerably higher than that of an iridium-platinum alloy of the same percentage composition. The alloy further possesses great hardness and tensile strength. Wires of the finest size are drawn with comparative ease.

Effect of Light on Decomposition Voltage

The paper on this subject by Alan Leighton, of Cornell University, reaches the following conclusions:

The decomposition voltage of a copper sulphate solution between platinum electrodes is not affected appreciably when the anode is illuminated by a mercury vapor lamp.

The decomposition voltage of a copper sulphate solution between platinum electrodes is increased when the cathode is illuminated by a mercury vapor lamp.

The light tends to make the solution and the deposited copper less stable. The latter effect is the greater under the conditions of the experiment.

It is possible to regulate the voltage so as to make copper precipitate on the shaded portions of the platinum cathode and not on the illuminated portion.

Graphite absorbs something from a copper sulphate solution, presumably a cuprous salt, which acts as an anodic depolarizer and can be removed by electrolytic oxidation. The reaction is accelerated by light.

Owing to this absorption the decomposition voltage for a copper sulphate solution with a graphite anode and a platinum cathode can be brought down temporarily to about 0.4 volt.

Rapid Refining of Copper with a Rotating Cathode

The paper on this subject, by C. W. Bennett and C. O. Brown, of Cornell University, points out that electrolytic refining of copper, as it is ordinarily done, is carried out with a current density of from 2 to 4 amperes per square decimeter of cathode surface. The amount of copper precipitated in one or two hours by a current of this density is small unless the cathode surface be very large.

For the purpose of demonstrating electrolytic refining as a laboratory experiment, the apparatus must be small, the

amount of metal deposited must be appreciable, and the time must be limited. If the cathode be rotated rapidly the current density can be increased greatly, current densities up to about 425 amperes per square decimeter having been used. With a small apparatus using current densities of this magnitude, sufficient amounts of copper for demonstration purposes can be deposited in a short time and appreciable amounts of the impurities may also be obtained as slimes.

The authors describe some tests on the rapid refining of copper to show that it could be done, and also with the idea of using it as a laboratory experiment. The experiments serve only to show that the same conditions obtain in rapid refining as in the commercial refining. They also give another instance of the rapidity of electrochemical work when the solution is stirred vigorously.

The experimental arrangement is described and illustrated.

The tests were made with a copper anode containing silver as only impurity, with an anode containing silver, arsenic and bismuth as impurities, and finally with an anode containing the usual impurities of copper anodes.

The tests show that electrolytic copper refining can be demonstrated in the course of an hour if a rotating cathode be used. The anodes may contain impurities usually found in commercial anodes, the demonstration being more striking if the impurities are present in amount approximating 1 per cent each. The anodes should be contained in a diaphragm, and the slimes may be removed partially with the diaphragm and the remainder by means of a stiff brush and water from a wash bottle. The deposited copper may be stripped off and sampled if aluminum cathodes are used.

Arsenic shows the largest tendency to contaminate the refined copper. It requires, however, the delicate Marsh test to detect this metal.

The statement that silver dissolves in neutral copper sulphate solution is probably an error.

Simultaneous Determination of Copper and Lead with the Rotating Anode

A paper by Arthur J. White, of Philadelphia, Pa., points out that, in electrolyzing nitric acid solutions of copper, lead tends to hold up some of the copper. However, an addition of sulphuric acid allows of copper being completely precipitated from a nitric acid solution while lead is being determined simultaneously on the anode, provided that the proportion of lead is not high enough to precipitate lead sulphate. This salt does not appear unless the proportion of lead to copper is greater than one to four, as the copper nitrate exerts a solvent action on smaller quantities.

When less than 0.15 gram of lead is present with 0.60 gram of copper, they are quantitatively precipitated in thirty minutes by a current of 8 amp at 6 volts.

The best proportions of acid are 4 cc. concentrated nitric acid and 10 drops of concentrated sulphuric acid in a volume of 70 to 80 cc. The anode is rotated at from 400 to 700 revolutions per minute and the copper is deposited on a 60-gram platinum dish.

The application to brass analysis is described in detail and some further observations are given which seem to warrant the application of the method to other alloys, provided they contain less than 2 per cent of arsenic or bismuth. These metals in small quantities act as reducing agents and require the addition of a little more nitric acid, whereas iron has an oxidizing effect and allows of less nitric acid being used.

Solid Thick Deposits of Lead from Lead Acetate Solution

The paper on this subject, by Prof. Frank C. Mathers, of Indiana University, emphasizes that "any soluble lead salt will give a solid, dense, coherent electrolytic deposit if the proper addition agents are used. Those solutions which do not give good deposits will do so when the proper addition agents are introduced. This theory cannot as yet be proved in all cases, but this paper gives the experimental proof in the case of lead acetate solutions."

Peptone was found to be the best addition substance for use in lead acetate solutions containing ammonium perchlorate. The effect of varying amounts of ammonium perchlorate, the effect of acetic acid, the effect of the quantity of peptone and of other factors were studied in detail.

Of other salts in place of ammonium perchlorate, sodium perchlorate and sodium naphthalene sulphate gave good deposits.

Among other addition agents the following were studied: Extract from feathers, casein boiled in acetic acid, casein modified by digestion with enzymes, tannin, meat extracts, vegetable extracts, essential and fatty oils, gums.

* * *

After a vote of thanks to all who had made this Colorado meeting so eminently successful, the meeting adjourned.

The final meeting held on top of Pike's Peak has been reported above.

The next meeting will be held in April, 1914, in New York City.

The following is a complete alphabetical list of those who registered at the meeting:

John C. Bailer, Golden, Colo.; T. F. Bailey, Alliance, Ohio; F. S. Bauer, Boulder, Colo.; E. A. Beck, New York City; F. D. Burr, Denver, Colo.; W. W. Case, Jr., Denver, Colo.; Regis Chauvenet, Denver, Colo.; W. R. Chesley, Golden, Colo.; G. B. Chorpene, Clarksburg, W. Va.; F. L. Clerc, Boulder, Colo.; G. H. Clevenger, Palo Alto, Cal.; C. L. Colburn, Butte, Mont.; A. E. Gerald Collins, Denver, Colo.; Mr. and Mrs. C. E. Collins, Denver, Colo.; C. W. Comstock, Denver, Colo.; W. D. Coolidge, Schenectady, N. Y.; E. L. Crosby, Detroit, Mich.; C. L. Devine, Clarksburg, W. Va.; D. C. Dodge, Denver, Colo.; Mr. and Mrs. J. V. N. Dorr, Denver, Colo.; C. J. Downey, Denver, Colo.; Wm. Dreyfuss, New York City; Mr. and Mrs. C. E. Eastman, Denver, Colo.; L. Ekeley, Boulder, Colo.; E. J. Ericson, St. Louis, Mo.; H. S. Evans, Boulder, Colo.; C. G. Fink, East Orange, N. J.; Herman Fleck, Golden, Colo.; Prof. and Mrs. F. C. Frary, Minneapolis, Minn.; R. H. Gaines, New York City; A. Galbraith, Chicago, Ill.; A. E. Gibbs, Philadelphia, Pa.; F. W. Gill, Arlington, N. Y.; Prof. and Mrs. S. L. Goodale, Pittsburgh, Pa.; J. R. Griffiths, Niagara Falls, N. Y.; H. M. Hall, Massena, N. Y.; C. A. Hansen, Schenectady, N. Y.; R. S. Hawley, Golden, Colo.; C. W. Henderson, Denver, Colo.; C. B. Hersey, Denver, Colo.; A. T. Hinckley, Niagara Falls, N. Y.; M. B. Holt, Denver, Colo.; A. J. Hoskins, Denver, Colo.; Mr. and Mrs. Wm. Hoskins, Chicago, Ill.; Miss Hoskins, Chicago, Ill.; J. A. Hunter, Boulder, Colo.; B. H. Jackson, Boulder, Colo.; D. R. Jenkins, Boulder, Colo.; H. W. Kellogg, Niagara Falls, N. Willard, Ann Arbor, Mich.; Miss C. Wilson, New York City; L. H. Wilson, Newark, N. J.; Harry J. Wolf, Golden, Colo.

Old Freibergers in America

The dinner in honor of Oberbergrat Dr. Richard Beck, Rektor of the Freiberg Bergakademie, Freiberg, Saxony, Germany, was held on Tuesday, September 9, 1913, at the Engineers' Club, in New York City. Many reminiscences told of former Freiberg days and several toasts were given. Mr. Franklin B. Guiterman, executive director of the American Smelting & Refining Company, acted as toastmaster. Dr. R. W. Raymond, Secretary Emeritus of the American Institute of Mining Engineers, responded to the toast "Reminiscences." Mr. Charles L. Bryden, head of the school of Metal Mining and Metallurgy, Scranton, Pa., responded to the toast "Old Freibergers in America," and Dr. Beck responded to "Alma Mater."

Dr. Beck, who has been visiting this country, attended the International Geological Congress in Canada. While there he was honored by the degree of LL.D. from the University of Toronto, Toronto, Ontario, Canada. Dr. Beck sailed for Europe on September 12.

The organization of the Old Freibergers in America is just one year old and the membership is over 60.

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver

Slime Agitation.—A new type of slime agitator is described in the monthly *Journal of the Chamber of Mines of Western Australia*, by Mr. H. B. WRIGHT. The device, which is illustrated in Fig. 1, is in use at the Great Boulder Perseverance mine, and has given improved results in extraction as compared with the ordinary type of mechanical agitator. It is known as the Wright-Jaentsch centrifugal aerator, and consists essentially in several pipes, say four, supported at an angle of 45 deg. in the tank and attached to the central revolving shaft. The pipes act as centrifugal pumps. Four pipes of 6 in. diameter, revolving at a rate which gives the outside ends a circumferential speed of 350 ft. per minute, have given good results. The author gives figures showing

FIG. 1.—WRIGHT-JAENTSCH CENTRIFUGAL AFRATOR

comparative tests between the centrifugal aerator and the ordinary mechanical agitator, working on the same pulp. The centrifugal aerator showed an increase of 7.5 per cent dissolved gold as compared with the mechanical agitator. Twenty-three of these aerators are in operation at the Great Boulder Perseverance; each vat is 20 ft. diameter and 4 ft. 6 in. deep, and the arms are rotated at 6.7 revolutions per minute. Three horsepower is required for each vat. The centrifugal force exerted is 6.5 lb. The greatest pumping effect is obtained when the pipes are just submerged, as then there is no hydrostatic head to be overcome.

The Cam & Motor Mill, Rhodesia.—One of the newest mills to be designed for the Hartley mining district of southern Rhodesia is the Cam & Motor. The method of treatment to be adopted was determined by laboratory tests supplemented by work in an experimental unit. The details of this work and an outline of the new mill are given by Mr. GORDON F. DICKSON in the August, 1913, *Mining Magazine*.

The ore has the following composition:

Silica	44.33	per cent
Iron pyrite	2.95	" "
Mispickel	2.15	" "
Stibnite	0.15	" "
Calcium carbonate	14.10	" "
Magnesium carbonate	26.10	" "
Graphite	Trace	

Laboratory experiments proved conclusively that an attempt to cyanide the raw ore would be unsuccessful, owing chiefly to the consumption of cyanide and the loss of free alkali through the decomposition of the existing minerals. Preliminary roasting indicated a high percentage extraction. A "sweet" roast was obtained in 45 minutes, and the extraction by leaching or agitation was 85 per cent to 80 per cent. The addition of both stibnite and graphite above the usual quantity was without appreciable effect, but care was required in the roasting operation to avoid fusing the stibnite. The carbonates of calcium

and magnesium were found to have a useful effect in maintaining the protective alkalinity of the solution. The dissolution of gold was rapid, and the consumption of cyanide was low.

In the operation of the experimental unit, all the data from laboratory tests were confirmed. On one occasion the extraction dropped suddenly from 85 per cent to 78 per cent, which was found to be due to the tendency of the ore to ball and sinter at the discharge of the furnace. This was remedied by lowering the temperature of the finishing hearth and opening side and end ports, whereupon the extraction rose again. Tests were made on the furnace, which is of the Edwards type, to see whether wood or coal was best for fuel. Under the economic conditions existing at the time, wood fuel proved economical. The furnaces have been constructed to burn wood, but can be changed to the coal-burning type when cheaper coal is available. One of the furnaces has been equipped with the Parkison patent fire-box of the type used at the Golden Cycle mill, Colorado Springs, Colo. This is designed to burn the coal on the producer principle and give a long incandescent flame.

Experiment has shown that 40-mesh is the economic limit of grinding. The sand and slime will be separated and treated by leaching and agitation, respectively. Caldecott cones and sand dewatering tables will be used to prepare the sand for leaching. The slime will be filtered in a vacuum filter of the fixed submerged leaf type. The entire plant will have a capacity of 15,000 tons per month.

Economics of Milling.—In the *Mining Magazine*, August, 1913, appears an article on this subject by Mr. GELASIO CAETANI, being one of a series of lectures delivered by him recently at Harvard University. In our issue for August, 1913, page 464, we published an abstract of the first of this series of lectures, on the principles of mill design.

Mr. Caetani first calls attention to the fact that the object of ore treatment is not to attain the highest metallurgical efficiency, and that high percentage of recovery is not necessarily an index to the efficiency of a metallurgical plant. Metallurgical recovery and economic recovery of metals are not of equal importance; the latter is paramount in practice, being the sole object of the plant. Economic efficiency is the resultant of several factors, chief among which are (1) metallurgical efficiency, (2) freight and transport charges, (3) smelter schedule, and (4) operating cost.

Economic efficiency and metallurgical efficiency may become almost identical when the final mill products are metallic, as for instance in the case of the production of gold and silver bullion from cyanide mills, or the output of metallic copper from mills in the Lake Superior region. But there are exceptions even in such cases. The author cites an example of a cyanide mill treating a gold-silver ore, the gold content of which is recovered quite readily, whereas the dissolution of the silver is slower and requires days of treatment to reduce the tailing to its minimum silver content. In such a case the economic efficiency and metallurgical efficiency will not be identical, and it may prove more profitable to leave the silver in the ore rather than spend additional time and money in extracting it.

The discrepancy between economical and metallurgical recoveries is most apparent in concentrating mills. It hinges on the fact that, under normal operating conditions, metallurgical recovery can be increased only by lowering the grade of the concentrates, and the grade of the concentrates can be raised only at the expense of metallurgical recovery. In order to operate the mill to the best economic advantage, the metal market, smelter schedule, etc., must be taken into consideration, in order that the greatest net profit may be obtained from the mill products. Discrimination between concentrate and tailing may be dependent entirely on the intrinsic value of the material itself.

In another case, the addition of low-grade middling to the concentrate will lower the average grade to a point where the unit prices paid for the metals are also reduced thereby, en-

tailoring heavy loss. As an example, assume an auriferous pyrite in quartz, the average concentrate from which will assay 2 oz. gold and 5.4 per cent lead. Suppose the smelter contract offers \$19 per oz. for gold; no payment for lead under 5 per cent, and 40c. per unit for contents above 5 per cent; treatment charge, \$5 per ton. In milling the ore we may get a middling containing gold to the value of \$6.65, 2.5 per cent of lead and 16 per cent zinc. At first sight it might appear that, since the middling contains \$6.65 in gold and the treatment charge is only \$5 per ton, there should be a net profit of \$1.65. But if 1 ton of the middling is added to 9 tons of concentrate, we will have an average grade of 1.83 oz. gold and 4.96 per cent lead. Consequently the value of the lead is entirely lost, with the result of a net loss per ton of concentrate. Mill operators sometimes delude themselves in the matter of shipping low-grade ore and mill products, and resort to the device of mixing them with higher grade material, not realizing that they are losing just as much as though the two products were shipped separately.

On the other hand, conditions may exist under which low-grade material can be thrown into the concentrate. The author cites an experience in which he disposed of the last spigot-discharge of a spitzkasten by mixing it with the slime concentrate. The profit of concentrating this spigot-discharge would have been but \$1.32 per ton of dry material treated, whereas, by mixing it with the slime concentrate and shipping to the smelter it netted \$4.69 per ton. The reason for mixing the two products was that the smelter would have refused to accept the low-grade spigot-discharge if shipped alone. Other instances of mixing concentrates to advantage may occur when the effect of mixing is to reduce the average grade of a deleterious constituent, such as zinc, without impairing seriously the grade of the valuable minerals. In this way a penalty on zinc may sometimes be avoided.

The author cites the operations of the Utah Copper Company as an example of the effect of large-scale operations on low-grade material. Success with a low-grade ore will depend on three factors: capacity, full load and continuity of operations.

In the case of combined concentrating and cyaniding plants, the two departments must be operated in such a way that the highest economic efficiency can be obtained. This will depend on the nature of the ore, the effect of the sulphides on the cyanide solution, the freight and treatment charges on concentrates, etc. Under some conditions it may pay to cyanide concentrates separately, and not ship them to the smelter. As an example, the practice at the Alaska-Treadwell is cited, where formerly it cost \$12 per ton to ship and smelt concentrates, as against a total cost of about \$5 for cyaniding at the mill.

These various considerations all emphasize the fact that the maximum economic efficiency and not maximum metallurgical efficiency is the ultimate object of the reduction plant. Many factors enter into the problem and it is the duty of the metallurgical engineer to watch the ever-changing conditions and to operate his mill in accordance with good business principles.

Zinc and Lead

Selective Flotation.—One of the recognized problems in slime concentration at Broken Hill, Australia, is the separation of galena from blende. Mr. J. Malcolm Newman, writing in the *Australian Mining Standard*, June 26, 1913, states that while it has been possible by flotation to recover lead, zinc and silver from the slimes, leaving a worthless gangue, it has been practically impossible to separate the two minerals into marketable products. Hitherto the separation has been attempted on concentrating tables and vanners, but the operation was unsatisfactory, even though the products could be mixed with those of higher grade and thus sold.

Recently efforts have been made to evolve "selective" or "preferential" flotation processes, whereby the galena and blende would be acted upon differently and thus yield separate concentrates. The Zinc Corporation is experimenting with two such processes, the Horwood and the Lyster. The importance of slime concentrating and separating processes is increasing with the deeper operation of the mines, for the minerals be-

come more intimately associated, and the opportunity for jiggling and other forms of coarse concentrating is decreased. In fact there is already a diminution in the amount of jiggling now done, and finer grinding becomes necessary to liberate the mineral particles. This produces more slime and increases loss of mineral; hence the need for methods of slime separation.

The Horwood process is better known than the Lyster. In the *Mining and Engineering Review*, Australia, July 5, 1913, some details are given of the operation of this process at the Zinc Corporation. The material treated is slime from the re-concentration section of the Minerals Separation flotation mill. It contains about 36 per cent zinc, 15 per cent lead and 22 oz. silver per ton. The slime is first thickened, then filter-pressed and dried with compressed air so that the cakes crumble when dropped from the press. The product is then roasted in an Edwards duplex furnace, at a temperature of 300 to 350 deg. The lead is sulphatized, but the zinc is unaffected, and in the subsequent flotation process only the latter floats. About 35 lb. acid and 2 to 3 lb. oleic acid are added per ton of slime. The mixture passes through seven flotation boxes, six of which produce zinc concentrate which is retreated in the seventh. The lead remains in the underflow. By this method it has been possible to produce lead concentrate containing 38 per cent lead, 8 per cent zinc and 42 oz. silver per ton; while the zinc concentrate runs as high as 50 per cent zinc, 7 per cent lead and 15 oz. silver per ton.

Less complete detail is given on the Lyster process, in the June 5 issue of the same journal. Current slime is first thickened and then fed to a centrifugal pump which is throttled to cause a violent agitation of the slime with oil and air which are admitted into the suction pipe by a small duct. The mixture is pumped to a spitzkasten with contracted overflow, in which the galena particles collect in a froth that overflows. The underflow, containing mainly zinc mineral, is then similarly treated in a second centrifugal pump with a further addition of oil, whereupon a zinc concentrate is obtained. Similar results have been obtained in Minerals Separation boxes, but the centrifugal pump is considered more efficient. The main point in the treatment seems to be successive additions of small quantities of oil followed by agitation, thus producing a fractional flotation of the different minerals. The report states that 55 per cent to 60 per cent lead concentrates have been obtained, and that a pure zinc concentrate has been made, thus demonstrating that the differential process can be applied to mixed slimes.

Tin

Electric Smelting.—Interesting details of experiments in smelting tin ore in the electric furnace are given by "A Special Correspondent" in the *South African Mining Journal* for June 7 and 14, 1913. After reviewing the present status of tin smelting in reverberatory furnaces, the author takes up theoretical considerations in electric smelting, and then cites results of experimental work. He concludes that under favorable conditions for power, the electric furnace process offers material advantages over reverberatory smelting.

The reduction of tin oxide by carbon may be assumed to occur according to the following two equations:

That part of the reaction takes place according to the second equation is indicated by the fact that CO can be seen burning at the mouth of the furnace. The author assumes that reduction takes place by both reactions, probably in equal proportions.

The combustion of 118 grams, or one gram-molecule, of tin into tin oxide will yield 145,300 gram-calories of heat, which is the amount of energy required for liberating 118 grams of tin. The combustion of 12 grams of carbon into CO₂ will yield 96,960 gram-calories; and the combustion of 24 grams of carbon into CO will give 58,000 gram-calories.

If the reduction occurs according to reaction (1) the energy requirement per ton of tin will be 145,300 = 96,960 = 48,340 kg.

calories per 118 grams tin, or 499,661 kg. calories per kg. tin, or 474 kw-hours per ton of tin.

In the same way the requirement according to equation (2) will be 855 kw-hours per ton of tin. Assuming that the reduction occurs to the extent of 50 per cent. of each reaction, the requirement would be, in round numbers, 665 kw-hours per ton of tin. In addition to this, a certain amount would be needed to heat the charge to the temperature of reaction.

Assuming that the ore contains 90 per cent tin oxide, we require 1280 kg. ore for each ton of tin. Experience has shown that the slag will amount to 16 per cent to 20 per cent per ton of ore, or say 220 kg. slag. The melting of a ton of slag requires, on an average, 500,000 gram-calories, or 130 kw-hours for each ton of tin. The heat capacity of the charge and molten tin may be set down as 65 kw-hours. Radiation losses are not definitely known, but are assumed to be as great as that consumed by the slag, or 130 kw-hours. The gases escaping from the furnace have a temperature of about 800 deg. C., and the loss from this source may be set down as 150 kw-hours per ton of tin. In summing up these items it appears that it should be possible to produce a ton of tin with the following expenditure of power: For the reaction, 665 kw-hours; slag loss, 130; specific heat of the charge, 65; radiation loss, 130; loss in gases, 150; total, 1140 kw-hours.

Current for the experiments under review was obtained from a Diesel engine plant, and was three-phase, 50 cycles, 650-675 volts. An oil-cooled transformer received current at 660 volts, and had four tapplings capable of giving 30, 40, 50 or 60 volts of 2500 ampere current.

The furnace was a shaft of special design, which is not described owing to pending patent applications. There were three carbon electrodes, 4 in. square and 4 ft. 6 in. long, cooled by water jackets, and suspended in such a manner as to permit fine adjustment. No direct arc was permitted to be formed, as this caused a great variation in the yield and in the working of the furnace. The charge formed a cone-shaped mass on the hearth, covering the reacting zone forming a small space filled with incandescent gas in which the reaction took place. Arrangement was made to prevent the escape of volatile metal, and only about 0.5 per cent of metal was thus lost.

At the start of a campaign of ten or twelve days, the furnace was preheated by a wood and coke fire. The charge contained 14 kg. culm for each 100 kg. ore. Current was first used at 60 volts, 1000 amperes per phase, and as the reaction proceeded this was changed to 40 volts and 2500 amperes, which current was maintained during the smelt. Metal was tapped half an hour after charging, and slag was drawn after the furnace had been running two hours. The proper operation of the furnace could be judged by the appearance of the slag: if it flowed freely, and was a dark brownish green color, the charge was right, but if the slag appeared sluggish and light brown a change was indicated.

Metal from the tap-hole assayed 98 per cent pure. In one case Bolivian ore of 49.9 per cent tin and 15 per cent iron was smelted for 10 days, with a net recovery of 92 per cent, running as high as 97 per cent recovery on one day. The grade of the metal from the furnace was raised to 99.75 per cent pure by simply blowing air through it.

The output, power consumption and loss in slag were found to be in close relation. It was possible to produce slag containing only 0.25 per cent metal, but this was not economical at the price for power. The output was only 6 to 8 cwt. per day, and the power consumption was 3000 kw-hours per ton of metal. On the other hand a slag containing 17 per cent to 18 per cent tin was produced, the output of metal being 1 ton and 11 cwt. per day, with a power consumption of only 1300 kw-hours per ton of metal. This slag would have to be re-treated.

It was finally found most economical under prevailing power

conditions to obtain a recovery of 96 per cent to 98 per cent, with a high power consumption.

The following figures refer to operations during the week of July 28 to Aug. 4:

Ore smelted—	
20,056 lb., 57 per cent tin.....	12,003 lb. metal
Scrap and refuse.....	2,324 " "
Tin produced	14,170 " "
Net yield	98.75%
Electrode consumption, per ton tin.....	28 lb.
Power consumption per ton tin.....	1,800 kw-hours

An Electrolytic Refinery in Wall Street

The Assay Office of New York

It has been said by a cynic that the only chemical compound with which modern financiers are thoroughly acquainted is water and that more than one triumph of modern industry has been acquired by utilizing the reaction between stock and water. Be that as it may. It is a plain fact that there is a real electrolytic refinery in Wall Street, New York City, small in size, it is true, but very big in the value of its output. This is the United States Assay Office. Next to it is the Sub-Treasury, and across the street is the office of J. P. Morgan & Company. No explanation is necessary to show that this electrolytic gold and silver refinery is at its logical place.

The relation between the Assay Office and the public is

FIG. 1.—ANODE MELTING FURNACES

twofold. First, the Assay Office buys impure gold and gold-silver alloys from the public. This may be the gold output of a copper refinery or of a cyanide mill or gold scrap from dentists, or gold imported from Europe, or old jewelry. Second, the Assay Office refines this gold and alloys for the various requirements of the public.

The metallurgical process carried out at the Assay office is, therefore, the separation of the gold from the silver and the other metal impurities and the production of the pure metals.

Formerly the sulphuric acid parting process was employed, but the electrolytic refining process has now been universally introduced into the United States Mints, and when a few years ago the New York Assay Office was damaged by fire and it became necessary to rebuild and reequip the Office thoroughly, it was decided to introduce electrolytic refining.

There is no necessity here to enter into all the intricacies of the electrolytic refining of gold and silver, since they have been dealt with in detail in numerous articles in this journal, written by the highest authorities. Reference to these articles must therefore suffice. The most important are by the inventor of the electrolytic gold refining process, Dr. E. Wohlwill, in our vol. II, p. 221 and 261, and vol. VI, p. 450; by Dr. D. K. Tuttle, who introduced the process in the Philadelphia mint and worked out a method of treating gold-silver alloys high in silver, vol I, p. 157, and vol. IV, p. 306; an article on the use of pulsating current in the Wohlwill gold refining process, vol

VIII, p. 82; further see the articles by Whitehead on the refining process in use at the San Francisco mint, vol. VI, p. 355 and 408 and by Dr. E. F. Kern, vol. IX., p. 443.

In buying gold or gold alloys from the public, the Assay Office has fixed only two restrictions. These are that the ma-

FIG. 2.—ELECTROLYTIC SILVER CELLS

terial shall contain not less than 20 per cent. of gold and silver and shall be worth at least \$100. The purchased deposits are melted down and molten dip samples are taken for assays.

Now a separation is made according to whether the per-

FIG. 3.—ELECTROLYTIC GOLD CELLS

centage of gold is less than 90% or more than 90%. In the first case the material goes to the silver refining room, in the latter case directly to the gold refining room.

FIG. 4.—GENERAL VIEW, DEPOSIT MELTING ROOM

The crucible furnaces employed for melting the material and casting into anodes for electrolytic silver refining are shown in Fig. 1, the electrolytic silver refining room in Fig. 2. The electrolyte is a solution of 3 percent nitrate of silver and 2 percent free nitric acid, this composition being carefully maintained. The tanks are of brown stoneware.

The anodes contain from 250 to 400 parts of gold, 150 or less of base metals, and the remainder silver (out of a total of

1,000 parts). The anodes are contained in muslin bags to retain the slime. The solution is stirred by a small belt-driven glass propeller in each tank.

The silver and base metals are dissolved in the electrolyte,

FIG. 5.—SWEEP HANDLING MACHINERY

but the silver alone is deposited on the cathode. The gold remains in form of slime in the anode bags. Every eight hours each cathode is lifted and the silver deposit is scraped off.

The current density is seven amperes per square foot.

The solution is frequently renewed. The gold content in the cathode silver is carefully watched and not permitted to exceed 2 parts in 100,000.

The gold refining room is shown in Fig. 3. Here the Wohlwill process is used. The cells are of Royal Berlin porcelain. The electrolyte is a gold chloride solution with some free hydrochloric acid. Pulsating current is used. The current density is 70 effective amperes per square foot.

FIG. 6.—REVERBERATORY MELTING FURNACE

The platinum and palladium recovered in this process are sold to the highest bidder.

Both gas and oil are used for melting purposes in the New York Assay Office, as a matter of precaution, to make continuous operation absolutely sure. The whole furnace equipment of the Assay Office has been supplied by the W. S. Rockwell Company of New York City, who designed several special furnaces for the special requirements of the Office.

Fig. 4 shows the room for the melting of the gold in crucible furnaces, Fig. 6 a reverberatory furnace, for special uses, like

the cupelling of base bullion which contains too much base metals to permit the application of the ordinary refining process.

Fig. 7 shows the testing laboratory where the different

FIG. 7.—TESTING LABORATORY

solutions are tested; Fig. 8, the office of the melting and refining department and the make-up room.

Fig 5 shows the sweeps department which has recently been installed in the basement. The equipment consists of a jaw crusher which crushes the sweeps to one-half inch or less in

FIG. 8.—OFFICE OF THE MELTING AND REFINING DEPARTMENT AND MAKE-UP ROOM

diameter, a grinding mill of the Chilean mill type, which grinds the sweeps under water so as to pass a 60-mesh screen to two settling tanks, and a steam dryer.

Homogeneous Lead-Lining and Lead-Nickel-Lining.—

We have received an interesting illustrated circular on this subject from Mr. Bartholomew Viola, 140 Liberty Street, New York, the American representative of Kuhnle, Kopp & Kausch. The "homogeneous lead-lining" is recommended particularly for vacuum appliances, for cookers, and for all lead-lined vessels, working under pressure. The lining is claimed to be so intimately adhering that the two metals are inseparable. Another interesting novelty of this firm are wrought iron and copper vessels with a lead-nickel lining, as a substitute for pure nickel vessels. The joining layer of lead is stated to combine the metals so intimately that they cannot become loose by heat or high pressure. The nickel coating is only a few millimeters thick so that the cost is not excessive.

A New High-Resistance Thermo-Electric Pyrometer

In the deservedly widespread use of the thermo-electric pyrometer the desirability of having the resistance of the millivoltmeter comparatively high has long been recognized, but there have been difficulties in producing such an instrument at a comparatively low cost.

For this reason low-resistance thermo-electric pyrometers have been very generally used, the resistance of the millivoltmeters varying between 2 to 5 ohms. With this type of instrument it is absolutely essential that the instrument be calibrated, together with the leads or connecting wires which

FIG. 1.—HIGH-RESISTANCE THERMO-ELECTRIC PYROMETER—INDICATING TYPE

are to be used, since any change in the length of these leads or any change in the length of the thermocouple furnished with the instrument will alter the true indication of the pyrometer so that serious errors will result. A change in the length of leads of 1 to 50 ft. is sufficient to make the average low-resistance pyrometer read 25° or more low and a change in the length of the thermocouple from 3 ft. to 4 ft. will make the same instrument read 20° more in error. For fairly accurate results, therefore, it is necessary to use the thermocouple and leads which are furnished with the instrument, or exact duplicates thereof—as long as a low-resistance millivoltmeter is employed.

It is true that for some time high-resistance galvanometers or millivoltmeters, portable in form, but not of the switchboard or wall pattern, have been produced abroad. They are, however, usually of the suspension type; that is, the moving element

FIG. 2.—INTERIOR CONSTRUCTION

is suspended from the end of a fine wire or metal strip. Aside from supporting the moving element the suspension strip has another function, and that is to restore the moving coil or element to its zero position. It, therefore, has to be comparatively long and also small in cross-section. It is also necessary before using the instrument to carefully level it.

The advantages, however, to be gained from a properly designed and constructed voltmeter of high resistance are very marked and some of them are as follows: Any change in the

length of leads connecting the thermocouple with the millivoltmeter from 1 to 1000 ft. will not change the indications of the instrument as much as 5°; nor will any change in the temperature of these leads introduce any error in the indications of the instrument; neither will the length of thermocouple, the size of the elements forming the thermocouple nor the length of the thermocouple inserted in the furnace change the indications of the instrument. All of these advantages are due entirely to the extremely high ratio of the resistance of the millivoltmeter in relation to the resistance of the thermocouple and leads.

The Brown Instrument Company, of Philadelphia, who have done so much in the past for pyrometry in this country, have for the past two years been conducting exhaustive tests to design an accurate, high-resistance, thermo-electric pyrometer. The result has been an instrument of the pivoted type; that is, a type in which the moving element or coil is not suspended from the end of wire or metal strip, but is absolutely supported by means of small hardened steel pivots in sapphire jewel bearings. The moving coil and pole pieces of the magnet have been so changed in design as to produce a magnetic flux of great intensity in the air gap in which the coil swings. This high-resistance instrument, having a resistance of 100 ohms, can be furnished in either the indicating type or the recording type.

In Fig. 1 is shown the standard type of indicating instrument of the high-resistance type made in the horizontal type so as to afford a long scale for easy reading. This type of instrument has a mirror under the scale so that absolute accuracy in readings can be secured.

In Fig. 2 is shown the interior construction of the high-resistance system showing the redesigned pole pieces and small moving element, the moving element having been lightened to a minimum.

The Brown Instrument Company has been able to design this system in such a manner that its cost is practically no greater than the cost of manufacturing the low-resistance instrument. The instrument can be used for either base metal or platinum thermocouples as desired and is recommended by the manufacturer for either type of couple. The same type of system is also used in connection with recording pyrometers.

Personal

Mr. Max F. Abbé, who has been engaged in the pulverizing and grinding machinery business for a great many years, is in Europe. The Abbé Engineering Company, 220 Broadway, New York City, manufacturers of pulverizing and grinding machinery, inform us that Mr. Max F. Abbé is their vice-president and is looking after their foreign interests in Europe.

Mr. Maxwell W. Atwater has been retained by the Ohio Copper Company to investigate the flotation process with a view to adopting it in the company's mill at Lark, Utah.

Mr. Albert J. Bone will be superintendent of the new smelting plant of the Granby company at Anyox, B. C.

Mr. B. A. Bosqui is to have charge of the new cyanide mill of the Commonwealth Mining Company, Pearce, Ariz. The mill will be ready for operation shortly.

Mr. G. Montague Butler, formerly assistant professor of geology and mineralogy at the Colorado School of Mines, has been appointed head of the department of geology in the newly organized Oregon School of Mines at Corvallis.

Mr. A. H. Case, formerly manager for the Tennessee Copper Company, Copperhill, Tenn., has accepted a position as consulting engineer for Lewisohn Brothers, New York City.

Mr. John Dern, who has been identified with several mining enterprises in Utah, has been offered an appointment in the diplomatic service under the present administration.

Mr. George Flint, Treasurer of the Radium Company of America, Sellersville, Pa., sailed on the S.S. "Caronia" for Europe. Mr. Flint's address is care London City & Midland Bank, London, England.

Messrs. C. H. Fulton and J. Burns Read, of the Case School of Applied Science, Cleveland, O., have been making a Western tour.

Mr. Bancroft Gore has been appointed professor of metallurgy in the Montana School of Mines, Butte, Mont. Mr. Gore was previously on the engineering staff of the Washoe reduction works of the Anaconda Copper Mining Company, and later smelter superintendent at the works of the Gatico Copper Mining Company, in Chile.

Mr. Sidney J. Jennings, vice-president of the United States Smelting, Refining & Mining Company, recently visited the company's properties in California.

Mr. R. L. Lee has been appointed assistant superintendent of the copper smelting works of the Central Chile Copper Company, Panulicillo, Chile.

Mr. John L. Malm, metallurgical engineer of Denver, has returned home from an extended business trip in the South and East.

The Ray Consolidated Copper Company announces the removal of its executive offices to 25 Broad Street, New York City.

Prof. Heinrich Ries is engaged by the Mines Branch of the Canada Department of Mines to make an investigation of the clays of western Canada.

Professor Albert Sauveur, of Harvard University, has been awarded the Elliott Cresson medal of the Franklin Institute, Philadelphia, in recognition of his work in metallography.

Mr. George Schneider has been appointed director of the mining section of the Colorado Industrial Exposition which is to be held in the Grand Central Palace, New York City, during the month of November, 1913.

Mr. Frank E. Shepard, of the Denver Engineering Works Company, has been to Ishpeming, Mich., to inspect the new iron concentrating mill of the American-Boston Company. Professor Robert H. Richards also visited the mill at the same time.

Mr. Joseph T. Singewald, Jr., is making an investigation of the ores of the Silverton, Colo., district on behalf of U. S. Bureau of Mines. The results of the investigation are expected to be of assistance in devising suitable methods of ore treatment.

Professor Alexander Smith, head of the department of chemistry at Columbia University, has accepted a position as professor in Princeton University for the year 1914-1915.

Mr. Bradley Stoughton, secretary of the American Institute of Mining Engineers, was guest at a luncheon of the Colorado Section of the Institute on September 16. The local section was duly organized with the following officers: W. J. Cox, chairman; C. J. Moore, vice-chairman; C. L. Colburn, secretary-treasurer; Richard A. Parker and Thomas B. Stearns, members of the executive committee.

Mr. L. A. Test has resigned his position as assistant professor of chemistry in the School of Mines, Rolla, Mo.

Mr. Pope Yeatman has gone to Chile.

Mr. Lewis E. Young, who recently resigned the directorship of the Missonri School of Mines, will devote part of his time to teaching in the department of mining engineering, University of Illinois, and will also take up graduate work in the department of economics.

Digest of Electrochemical U. S. Patents

Prior to 1903.

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

REFINING METALS (Continued).

494,231, March 28, 1893, Charles B. Schoenmehl, of Waterbury, Conn., assignor of one-half to Alden M. Young, of same place.

Relates to refining metals using the same as secondary electrodes in a suitable electrolyte. For copper, an electrolyte of copper sulphate is used. The plates of crude metal are coated on one side with carbon or graphite, and the metal from the adjoining plate deposited upon the graphite coating. The patent refers to his copending application which became patent No. 494,232.

494,232, March 28, 1893, Charles B. Schoenmehl, of Waterbury, Conn., assignor of one-half to Alden M. Young, of same place.

Relates to apparatus for the refining of copper, etc. The crude metal is used as secondary electrodes. The vat contains supports for removable electrode holders, the holders serving also to maintain a uniform distance between all the plates, and also to support a diaphragm of a suitable fabric to protect the cathode side from floating impurities. The sides of the vat are perforated above the bottom, and communicate with parallel electrolyte vats, through which a constant circulation of electrolyte is maintained. The holes are so located as not to disturb any sediment at the bottom of the vat.

505,846, Oct. 3, 1893, Pierre DeP. Ricketts, of New York, N. Y.

Relates to a process of refining crude nickel, nickel alloys and other nickelliferous products. The product is first smelted or otherwise treated to reduce the nickel to the metallic state, and to remove most of the impurities. The metal thus obtained is rolled into suitable anodes and electrolyzed in an acid bath containing alkali salts, such as sulfuric acid containing sodium or ammonium sulfate, etc. During electrolysis the nickel forms a double sulfate with the alkali, which double sulfate is insoluble in the acid solution and precipitates to the bottom; it is subsequently collected and may be used for electroplating purposes, or it may be retorted; the nickel oxide thereby obtained is nearly pure and may be reduced by carbon. With nickel alloys as anodes, the remaining metal is either deposited during the electrolysis, as in the case of copper, or remains in solution, as in the case of iron.

514,275, Feb. 6, 1894, Lingan S. Randolph, of Baltimore, Md. Relates to the refining of copper or other metals by electrolysis in a cell in which the crude metal sheets are disposed horizontally and electrolyzed as secondary electrodes, the current entering the cell through the bottom electrode and passing out at the top. The plates are suitably separated by glass, etc., the electrolyte is circulated so as to keep the slimes in suspension and carried out of the tank where they may separate and the solution be filtered before returning to the cell. The anodes are preferably rolled or pressed, but may be cast.

514,276, Feb. 6, 1894, Pierre deP. Ricketts, of New York, N. Y.

Refers to his prior application, which became patent 505,846, of which this is a division, and relates to the method of separating nickel contained in nickelliferous bodies from the other metals and impurities combined therewith, consisting in immersing and dissolving the nickelliferous bodies in suitable acids; in adding thereto sulphates of ammonia or other similar ammoniacal salts, so as to form and retain a bath having an acid reaction of such composition as to dissolve the copper and nickel and retain the former in solution and form with the latter insoluble salts; and in causing an electric current to traverse the bath continuously from a suitable positive terminal to a suitable cathode, placed therein, whereby the copper is deposited upon the cathode and the nickel salts are precipitated to the bottom of the bath; in collecting the precipitated salts and dissolving the same in water, separating the insoluble impurities contained therein; evaporating the solution to dryness and heating the residue in a retort, whereby the ammoniacal products are collected and condensed for further use, and the nickel residue refined in any convenient manner.

515,763, March 6, 1894, Carl von Grabowski, of Eisleben, Germany.

Relates to the purification of sulfate electrolytes or other solutions containing a plurality of metals and arsenic and an-

timony. A sulfuric acid solution containing metallic sulfates is evaporated until it reaches a specific gravity of 52 deg. Baumé, the copper and other sulfates being crystallized out. The resulting solution is electrolyzed with a current density of 60 to 80 amp per square meter of anode surface using anodes and cathodes of lead or copper. Arsenic and antimony are electrodeposited and the solution entirely freed thereof. If the concentration exceeds 52 deg. Baumé, arsenic and antimony sulfides will be electrodeposited, the sulfuric acid being decomposed with liberation of hydrogen sulfid.

532,209, Jan. 8, 1895, Bernard Moebius, of New York, N. Y. Relates to a method and apparatus for refining metals, such as gold, silver, copper, bullion, etc. The apparatus consists of a horizontal tank in which is a traveling belt cathode preferably of thin metal, and above the cathode a series of removable trays having porous bottoms, the trays constituting anode compartments. The traveling cathode discharges its granular deposit upon a second traveling belt which removes it from the tank. The bullion to be separated is cast into anode plates and immersed in an electrolyte consisting of a strong solution of sodium or potassium nitrate sufficiently acidulated with nitric and sulfuric acid to keep some of the silver and all of the copper in solution. A current of small electromotive force is used, the silver being deposited upon the cathode in a loose, spongy state or in crystalline form. The copper is dissolved from the anode but remains in solution, while the gold and platinum metals are retained in the anode compartment, together with some lead peroxid, silver peroxid, and other impurities. Attention is directed to the improvement described in patent 592,097.

Book Reviews

Safety. By Wm. H. Tolman, Ph.D., and L. B. Kendall. Octavo (14 x 22 cm.), 422 pages, numerous illustrations; price 3.00 net. New York and London: Harper & Brothers.

This is an interesting and valuable book on methods for preventing occupational and other accidents and disease, the senior author being the Director of the American Museum of Safety. It discusses sources of danger and their removal in a dozen general types of works or factory, industrial hygiene in various occupations, and the social welfare of workmen in general. The information and advice are suitable and valuable to both employers and employees, while the general public will also find the book highly interesting and profitable reading.

General and Industrial Organic Chemistry. By Dr. Ettore Molinari, Professor at the Luigi Bocconi Commercial University, Milan. Translated by Thomas H. Pope of the University of Birmingham, England. Large octavo (15 x 25 cm.), 770 pages, 306 illustrations. Price, \$6 net. Philadelphia: P. Blakiston's Son & Co.

Dr. Molinari wrote also a companion volume on Inorganic Chemistry, which has been reviewed in the January, 1913, issue of this journal (Vol. XI, p. 61). The two volumes supplement each other and really constitute one work.

After a short introduction on the properties of organic compounds in general the treatise is divided into two parts; derivatives of methane and cyclic compounds. The former embrace the saturated hydrocarbons, halogen derivatives, alcohols, derivatives of alcohols, acids, derivatives of acids and aldehyde alcohols; the latter all other organic compounds. Under each individual substance there is given its history, properties, preparation in the laboratory, industrial preparation and commercial value and uses. The commercial relations, price, imports, exports and consumption, are a particular feature, intended to give the reader or student the proper idea of the commercial importance of the material.

The information is in general commendably up to date; one exception is the antiquated calculations of the temperatures produced by the burning of various explosives, which need

radical revision using modern values for specific heats of the gases produced. The calculated values given are impossible and make scientific calculations look ridiculous. The book, however, as a whole, is a most valuable and commendable work.

* * *

Iron and Steel. By O. F. Hudson, M.Sc., with a section on Corrosion by Guy D. Bengough, D.Sc. Octavo (14 x 22 cm.), 173 pages, 45 illustrations; price \$2.00 net. New York: D. Van Nostrand Co.

This short treatise is one of the series of "Outlines of Industrial Chemistry," edited by Dr. Bengough, and is intended to present to engineers, users of metals and students of metallurgy the more important principles of the metallurgy of iron and steel. The seventeen chapters of five to fifteen pages each (average length ten pages) deal with mechanical testing, production of pig iron, properties of cast iron, foundry practice, malleablized cast iron, wrought iron, crucible steel, cement steel, Bessemer process open-hearth and electric steel, mechanical treatment of steel, impurities in steel, study of iron-carbon alloys, heat treatment of steel, special steels, steel castings, welding, corrosion.

Inspection shows the various chapters to be well and correctly written, and to contain as much information as could be expected in such small space. The work, however, gives only the merest outline of a very large field, making it suitable for beginners only or for those desiring only a general review of the present status of the subject.

* * *

Das Materialprüfungswesen. Edited by Prof. Dr. F. W. Hinrichsen. 25 x 16 cm. (10 x 6½ inches), 607 pages, 215 illustrations. Price, bound in paper, 18 marks. Stuttgart: Ferdinand Enke.

Dr. Hinrichsen, who is connected with the Institute of Technology of Charlottenburg and the Testing Bureau of Berlin-Lichterfelde, has had the co-operation of Dr. Martens and twelve of his assistants of the Berlin Testing Bureau, and of Dr. Maffia of the Dresden Testing Laboratory, in producing this review in condensed form of the whole field of testing materials mechanically, physically and chemically.

This is an immense field to cover and necessitated restricting the treatment to the best methods now in use in each case. The work is taken up in the following order: Metals and Alloys, Ores, Pigments, Building Materials, Paper, Ink, Textiles, Fuels, Water, Fats and Oils, Rubber, Leather, Explosives, and each chapter or part of a chapter is handled by a specialist—in most cases by the best specialist in that line in Europe.

Under these circumstances the work is exceptionally valuable and accurate, and well worth getting by anyone interested in the general subject or in any one of the various materials discussed.

* * *

The D'Este Steam Engineers' Manual. With electrical appendix by Charles Penrose, E. E. Second Edition. 117+356 pages, with numerous illustrations. Price \$2 net. Boston, Mass.: Julian D'Este Company.

This manual which here appears in its second edition has been very considerably enlarged by the addition of an electrical appendix, prepared by Mr. Penrose. The steam section comprises 117 pages, the electrical appendix not less than 356 pages.

The book does not compete with specifically electric handbooks, but retains its character as a steam engineering handbook. In the electrical appendix the endeavor is therefore to emphasize those features of the practical side of electrical engineering which are of particular interest and importance to the steam engineer who has to do with electrical apparatus. The endeavor of Mr. Penrose not to shoot over the heads of his readers is very evident and we believe that practical steam engineers will find the book very useful. The old friends of the first edition should certainly become even better friends of the second edition.

Some Aspects of the Half-Watt per C. P. Tungsten Lamp

The two papers by Dr. I. Langmuir published elsewhere in this issue on the new nitrogen-filled tungsten lamp mark a new milestone in the development of the electric incandescent lamp.

Oct. 21, 1879, is considered as the birthday of the electric incandescent lamp, since on that day Edison carbonized a piece of cotton sewing thread bent into a loop of horseshoe form and had it sealed in a glass globe from which the air was afterwards exhausted. Edison's genius solved the carbon-lamp problem so completely that for somewhat like twenty-five years the carbon lamp reigned supreme in incandescent lighting, until a little over ten years ago the first metallic-filament lamp appeared.

With the single exception of the Nernst lamp, which was an ingenious invention and a big thing in its day, but is now only of theoretical and historical interest, the whole development of the last ten years has been along the line of the metallic filament. The metallized carbon filament may first be mentioned which reduced the specific consumption of 3 watts per cp of the ordinary carbon lamp to 2.5 watts per cp. Then came the osmium lam, the tantalum lamp (2 watts per cp), the tungsten lamp (1.25 watts per cp), the ductile tungsten lamp (1 watt per cp), and now we have the nitrogen-filled tungsten lamp consuming but 0.5 watt per cp.

The general public is liable to look at this development as a triumph of electrical engineering. In reality it is step by step one continuous triumph of physico-chemical research. Just as in gas lighting and in electric-arc lighting the most notable advances—the incandescent gas mantle and the impregnated carbons of the flaming arc—have been the result of the work of the chemist, thus the evolution of the metallic-filament just sketched shows one pre-eminent leitmotiv of physico-chemical nature.

If we consider the light given out by an incandescent lamp as "pure temperature radiation," the radiation laws indicate that any increase in the operating temperature of the radiating filament must vastly increase the efficiency for two reasons: Firstly, because according to the Stephan-Boltzmann law the total radiation increases as the fourth power of the absolute temperature, and, secondly, because according to Wien's law of the displacement of the maximum in the energy spectrum, more of the radiation falls within the range of visible spectrum. Hence increase in temperature filament has been the leitmotiv.

Naturally the first limit to such increase is set by the melting point of the filament, and this consideration is clearly indicated in the historical development by the successive experimentation with metals of higher and higher melting points. Osmium was followed by tantalum and tungsten. Soon, however, it was recognized that before the fusion point could be reached, evaporation of

the metal, resulting in blackening of the globe, would set a limit to the operating temperature of the filament. And it is this limitation which has now been overcome by the nitrogen-filled tungsten lamp. Evaporation is held back or controlled within inoffensive channels and this makes it possible to increase again the operating temperature of the tungsten filament with such a gain of luminous efficiency that in spite of the loss by conduction of heat through the nitrogen atmosphere the specific consumption in watts per candle-power is cut in half.

The whole development has been international. In Europe Baron Auer von Welsbach and, in connection with the tantalum lamp, the chemists of Siemens & Halske have been pre-eminent among many active and able workers. But credit for the metallized-carbon lamp, for ductile tungsten, and for the nitrogen-filled tungsten lamp is due solely to the United States. Glorious work has been done by the Research Department of the General Electric Company under the genial leadership of Dr. W. R. Whitney. With his staff of able co-workers, men like Dr. W. D. Coolidge, he has directed extended researches on a strictly scientific basis, leading to the invention of ductile tungsten by Dr. C. G. Fink and the invention of the nitrogen-filled lamp by Dr. I. Langmuir.

Thus there should be glory enough for all. But that the new nitrogen-filled tungsten lamp is something great, is indicated in a rather amusing manner by the way how it has been announced in Europe. At the last convention of the German Association of Electrical Engineers Herr Salomon said: "Recently the Allgemeine Elektrizitäts-Gesellschaft has succeeded by the application of new means in making tungsten-filament lamps which have all other advantages of these lamps but consume only 0.5 watt per candle" (*Elektrotechn. Zeitschr.*, Aug. 14, 1913, page 955). Not one word about the inventor. Perhaps more diplomatic was the announcement in Great Britain "that the credit of evolving this lamp belonged to the British Thomson-Houston and associated companies, having been developed first at the laboratory of the Schenectady works by Mr. W. C. Whitney" (*London Electrical Engineering*, Aug. 28, page 487). Well, the compliment paid indirectly to physico-chemical research in the United States is genuine and sincere.

Cyanide from Beet-Sugar Waste

The removal of a $1\frac{1}{2}\%$ *ad valorem* protective tariff on imports of potassium cyanide directs attention to the status of cyanide manufacture in this country and abroad. The largest domestic manufacturer, combatting the proposal to place cyanide on the free list, stated that 5000 tons of sodium cyanide were manufactured in the United States in 1912, and urged the retention of the duty.

Chemical manufacturing in this country undoubtedly suffers by comparison with the much older and more highly developed industry in Europe, particularly in Germany. The German manufacture of alkali cyanide as a by-product from beet-sugar molasses is a case in point. It appears that beet-sugar molasses contains about 5% potash and 2% nitrogen. If the sucrose is precipitated and removed, the residue becomes a concentrate of potash and nitrogenous materials; and it is this residue, molasses *schlempe*,

which the Germans convert partly into alkali cyanide. The residue is distilled at about 400° C., yielding gaseous compounds of nitrogen which, on being heated to about 1000° C., synthesize ammonium cyanide. This is decomposed by sulphuric acid, forming ammonium sulphate and hydrocyanic acid, the latter being then absorbed in sodium hydroxide. The quantity of sodium cyanide thus produced annually in Germany approximates 5000 tons, which finds a market in South Africa.

We too have a large beet-sugar industry and might convert molasses partly into cyanides; but under our conditions the saccharine by-product finds use largely as a component of food for cattle and other stock. The case is only one of many which illustrate the difference in methods between a highly organized old industrial community on the one hand, and a new country rich in natural resources on the other. It would be a big mistake to conclude that what is industrially successful in the one would be *co ipso* economically promising in the other.

Leaching Copper Ores and Tailings

The great amount of experimental work going on in the West in the leaching of low-grade copper ores and tailings, calls attention to a marked change in the attitude of metallurgists toward such processes. Whereas, not many years ago, the hydrometallurgy of copper was regarded with suspicion, and the men who advocated it met with scornful criticism, today the tables are turned and some of the best talent in the country is engaged in this work, with reasonable prospects of success. The change is a consequence of technical progress, stimulated by the necessity of making the most of our resources; but in a broader light it is only one phase of the tendency toward a more general consideration of hydrometallurgical methods. With the realization of the limitations of current processes, attention is being directed toward chemical treatment in the wet way.

It is recognized that in the leaching of copper ores, no method of general application is likely to be evolved; and that each case presents a separate problem, varying with the material to be treated, the locality and the prevailing economic conditions. Leaching, of itself, is not a difficult feature; nor is the preparation of ore to make it amenable to leaching an insurmountable obstacle. Common salt and sulphuric acid are plentiful and cheap commodities. The latter can be produced as a by-product where ores are roasted on a large scale, so that with an increase in demand a plentiful supply can be assured.

Precipitation of the copper from solution appears to be the stumbling block and the point on which the different processes now under way are most widely divergent. Electricity, hydrogen sulphide, and iron are the agents thus far proposed and used. All three are in use in Montana: electricity at the Butte & Duluth and the Bullwhacker, hydrogen sulphide at Anaconda, and iron at the plants precipitating mine water. Electrolysis and precipitation on iron have been widely experimented with in Arizona. In the electrolytic work at one plant, the sulphur dioxide gas obtained from roasting the ore is bubbled through the electrolytic vats to prevent polarization.

Scrap iron is almost always suggested as a precipitant, but usually without thought of the difficulty of securing an

adequate supply in the isolated districts where much of the leaching is done. Further, the efficiency of precipitation and the quality of the precipitate are affected by the nature of the scrap, as Mr. Febles showed in his paper at the Butte meeting of the Institute. On the other hand, while the use of a suitable grade of pig iron is not commonly considered, it is not impracticable in certain localities. In the Southwest, for example, both domestic and imported pig iron can be bought for \$11 or \$12 per ton, and probably laid down at the plant for less than one per cent per pound. Compared with poor quality scrap at Butte for \$7 or \$8, and old rails at \$11 per ton, the use of pig iron might not be out of the question in certain localities.

Another phase of iron precipitation, however, is more interesting. Iron sponge, or metallized iron oxide, can be produced by the "step-reduction" of iron ore, as in the Jones process which was tried in Michigan. This reduction process has been applied to pyritic calcine, obtaining thereby spongy iron or iron dust, according to the fineness of the material. Experiments have shown this to be an excellent precipitant of copper. The advantageous feature of the method lies in the fact that sulphuric acid for leaching could be made from pyrite, and the resulting calcine reduced to iron sponge for precipitation of copper solutions. It might even be possible to roast chalcopryite, leaching the copper with the acid formed from the roaster gases, dry and reduce the iron oxide residue and use it as a precipitant. While this method of operation has been tried only in a small way, it is known that the investigators are hopeful of its success under suitable conditions.

The American Iron and Steel Institute.

Although it is four and a half years since the American Iron and Steel Institute was chartered, it is hardly two years since the organization began to secure papers of importance. As The Iron and Steel Institute—with the necessary accent upon the particle—is quite cosmopolitan in character and indeed numbers in its membership many American steel manufacturers and engineers, one is naturally eager to seek means for differentiating the two organizations. The Institute, which has its headquarters in England, in plain terms, can be held to "fill the bill" for the iron and steel industry of the world unless, or until, another organization shows a *raison d'être*.

The American Institute is doing well, for so young an organization, in defining a place for itself, and the papers presented at the semi-annual meeting, Oct. 24-25, in Chicago, make a fair showing when viewed in the general sense, and serve in particular to indicate that the American Institute has work of a somewhat different nature from that which the cosmopolitan Institute has done so well for many years.

Upon all subjects it is hazardous to generalize, but if the statement be not proved accurate it is at least suggestive that while the papers of the older Institute seem to be prepared largely by the men who study steel, the papers of the American Institute are prepared by those who make and sell steel. They deal less with molecular structures and more with how to get out the tonnage and how to adapt steel to new and specific uses. As to one point of differentiation a generalization is accurate, that the cosmo-

politan Institute never deals even remotely with commercial practices, its constitution forbidding, while the American Institute does. Three years ago a paper was presented, and discussed by the most prominent steel manufacturers in the country, on "Contract Obligations in the Steel Trade" and a year and a half ago a paper upon the same subject was given. The object was that contracts for the sale of finished steel products should be binding, instead of being mere options given by seller to buyer. The aim is to correct a crying evil which exists in the American trade but which is not found abroad. Unfortunately, no improvement can be traced directly to the airing given the subject before the Institute.

At the recent Chicago meeting another important commercial subject was discussed, that of "extras," several speakers insisting that the recognized extras represent an added cost of manufacture and are thus neither a bonus nor a source of extra profit, while some of the speakers specifically gave the advice that if a manufacturer desired to name a particularly attractive price he should do so by reducing his base price and not by conceding one iota of the extra. In any branch of manufacture it is recognized that the first step towards removing a difficulty must be to find and define its cause. Commerce, it appears, does not necessarily accept this principle, for one cannot find in these papers a clear statement of why extras are cut. In the case of many extras, and nearly all those which arise from the piece being of a particular cross-section, the extra cost upon which the card extra is based is a cost due to time lost in roll changing or to reduced output of the mill while actually rolling the material. When mills are running at less than full capacity this element of cost is reduced, possibly to insignificant proportions, and it is a recognized fact that it is when the market is dull and mills are not fully employed that extras are cut. This is the explanation. We do not for an instant imagine it is without the ken of those who read the papers at Chicago, our object being merely to point out that it escaped specific mention, whereas had the subject been mechanical, metallurgical or chemical, instead of commercial, the cause or the evil would have been stated as the foundation of the paper. Hence it may be questioned whether as much light can be thrown upon the problems of selling as upon the problems of manufacturing, by the reading of papers.

However, we must remember there was a time when papers upon manufacturing processes were rare because those who had knowledge preferred almost invariably to keep it to themselves. Their view broadened eventually. The reading of papers upon commercial subjects is in its infancy and in time the subjects may be handled with adequate precision and frankness.

With enterprise and directness characteristic of its locus, the American Iron and Steel Institute invites the user as well as the producer of steel to contribute to its meetings, and so at Chicago there was a paper on the steel car wheel by a producer, followed immediately by a paper from the superintendent of motive power of the Pennsylvania Lines West, giving the viewpoint of the user. Obviously this is practical, and bound to promote real progress, for after all the end of all endeavor with respect to steel is to make it render more and more service to man.

Readers' Views and Comments

"Hydrometallurgy—Joys of Its Theory, Woes of Its Practice"

To the Editor of Metallurgical & Chemical Engineering:

Sir:—In your October issue I note Mr. Warren F. Bleecker's review of my article, published under the above caption, in the September number. In Mr. Bleecker's comments, page 539, he draws the inference that I made specific allusion to a difficulty in the Malm process of dry chlorination.

The stoppage in question was not incidental to the Malm process, nor was the impurity calcium sulphate. So far as I personally am concerned the correction is of no value, but I wish to relieve Mr. Malm from the implication.

Golden, Colo.

REGIS CHAUVENET.

Slime Thickeners

To the Editor of Metallurgical & Chemical Engineering:

Sir:—I note in your issue of September, 1913, page 528, in the report of the very valuable paper of Mr. Hayden on Slime Concentration at Anaconda, that you quote the following:

"The Dorr tank has nearly the same settling capacity per square foot of settling area as the smaller unit," etc.

As compared with this information obtained from the Anaconda tests, we have advices from one of the largest gold-mining companies, which has installed a 44-ft. thickener to operate against 20-ft. settling tanks previously used, that they apparently get an increase of capacity per square foot of 5 to 10 per cent. We have also the statement of the superintendent of one of the largest copper companies in Nevada, who put in Dorr thickeners after operating small cones for a number of years, and who says:

"We are getting most excellent results from the thickener, using the overflow of two thickeners for wash-water on forty Wilfley tables and occasionally a surplus for use as wash-water on vanners. One thickener 17 ft. diameter by 9 ft. deep has a greater capacity than twelve 8-ft. cones, for the reason that there is only one unit to watch instead of twelve, without the constant result of feed to twelve cones becoming unbalanced. Also the 1¼-in. spigot used on the thickener requires no attention compared with the dozen ¾-in. spigots of the cones. We have never had a moment's trouble with the thickeners in any way since their installation."

It will be noted, of course, that the difference between the results obtained here and those at Anaconda is that the latter were compared with tests made on cones and not in regular mill operations.

JOHN V. N. DORR.

Denver, Colo.

High-Resistance Pyrometers

To the Editor of Metallurgical and Chemical Engineering:

Sir:—It is seldom that we have occasion to take exception to anything published in your journal, but the article on "a new high-resistance thermo-electric pyrometer," published on page 596 of your October issue, contains obvious errors.

Setting aside the fact that our company has been building high-resistance galvanometers of the pivoted type for more than four years, with a resistance averaging from 75 to 100 ohms, depending upon the range of temperature to be covered, the statement concerning the effect of the length of leads upon the accuracy of the instrument is obviously wrong. The resistance of 1000 ft. of No. 12 wire is 1.5 ohms, and the resistance of 1000 ft. of No. 14 wire is 2.5 ohms, hence the former would cause an error of 15 deg. at 1000° F., and the latter an error of 25° in the reading of the instruments at the same temperature, these errors being doubled at 2000° and tripled at 3000° F. If the ordinary acceptance of the wording is taken and a distance of 1000 ft. between the instrument and thermocouple is meant, the errors illustrated above would be

doubled, making a maximum error at 3000° F. of 90° for the No. 12 wire and 150° for the No. 14. For our "high-resistance" instruments we are contenting ourselves with the statement that a variation of from 50 to 100 ft. in distance makes no appreciable error in the reading.

The statement relative to the effect of a change in length of leads on the average low resistance instrument contains an even greater error. Assuming an instrument to have a total resistance of 5 ohms, including the length of the leads, the elimination of 50 ft. in distance of these leads would mean an elimination of 25 ohms, or 1/20th of the total resistance, causing an error in the reading of the instrument at 1000° of 50°, 100° at 2000° and 150° at 3000°. With an instrument having a total resistance of 100 ohms, a change of 100 ft. in length of leads would mean a variation in resistance of .5 ohm, causing an error at 1000° of 5°, 10° at 2000° and 15° at 3000°. In all these illustrations the nature of the error would be governed by the insertion or removal of the resistance in question, the insertion of resistance causing the instrument to read lower, the removal of resistance causing it to read high. For this reason the examples quoted above are not mathematically correct, as the exact percentage of error would depend on whether the leads were lengthened or shortened.

We also wish to state that we have in our laboratory a wall type pyrometer built by Siemens-Halske Co., having an internal resistance of 152 ohms and to our knowledge they have been building this type of instrument for a number of years.

D. C. DRAPER.

Thwing Instrument Company,
Philadelphia, Pa.

* * *

To the Editor of Metallurgical and Chemical Engineering:

Sir:—The article on a new high-resistance pyrometer, published on page 596 of your October issue, claims a new achievement in pyrometer apparatus.

In short, the article refers to a pyrometer indicator having an internal resistance of 100 ohms, the instrument being of the switchboard or wall pattern, and it is stated that this is a new achievement. Actually, the reader is given no opportunity to judge of the reasonableness of this claim because other factors are not mentioned. A galvanometer or millivoltmeter might have 100 ohms resistance for say, 50 millivolts, which is about the range of instruments generally used with base metal couples and the same instrument would have about 40 ohms when used with the range of only 20 millivolts, which is the approximate electromotive force of platinum-rhodium couples when used for their highest possible readings. Still further information as to what portion of the internal resistance is in copper and what in wire having negligible temperature co-efficient, would be necessary in order that one might intelligently pass on what has been achieved in an instrument of this general character.

But while that is highly important, it is not at all the point we wish to cover here and we refer to it to call your attention to the fact that the achievement represented in the instrument described in the above mentioned article is not proven by the necessary data in regard to the instrument itself but reliance for proving the point of new achievement rests entirely upon a statement in regard to what has been achieved or not achieved by others. This statement we now quote:

"It is true that for some time high-resistance galvanometers or millivoltmeters, portable in form, but not of the switchboard or wall pattern, have been produced abroad."

This statement does gross injustice, not simply to ourselves, but to many other makers of high-grade scientific apparatus. Pyrometry has been of invaluable assistance in metallurgical and other industrial work involving high temperatures.

Factors that are necessary for a high order of accuracy in temperature measurement are not known to all who wish to acquire that order of accuracy and the article we refer to is well adapted to mislead many of your readers.

We shall refute the statement on which that article mainly relies, by some data on our own instruments after here making clear that the statement does injustice to apparatus of some other makers as well as ourselves.

Our 1908 catalog illustrates and describes a wall-pattern high-resistance instrument, not of the suspended-coil type, not requiring to be set level; as well as a portable instrument of the same general type. Those instruments were furnished with 100 ohms for 20 millivolts with platinum-rhodium couples and when used with our base-metal couples they were furnished with 280 ohms internal resistance. These instruments were in every way a success and have been sold extensively for over five years in the face of much opposition by those who were not at that time making instruments anywhere near approaching such resistance, and were pointing out at that time that high resistance was not really so very necessary.

In the last five years we have been making pyrometers with base-metal couples and the resistance as high as 400 ohms in the indicator with 87 per cent of that resistance in wire of negligible temperature coefficient on the series coil and all of these instruments have been made in both portable form and the wall pattern or switchboard type. Yet according to the article above mentioned, that has not heretofore been done.

Gold in Sea Water

To the Editor of Metallurgical and Chemical Engineering:

Sir:—Professor Regis Chauvenet, in his very interesting article on Hydrometallurgy, on pages 486 to 491 of your September issue, has apparently taken someone else's word for some of his statements, without trying to substantiate them for himself. He says "for many years a paragraph had been floating around the world stating that sea water contains a definite proportion of gold. One metallurgist has taken the trouble to trace the statement to its source, with the result that the trail 'ran up a tree.' No authoritative statement of the contents of gold 'per ton of ocean' could be discovered. * * * Possibly there is some infinitesimal trace of gold there. Certainly there is not that much (1 grain per ton)."

If Professor Chauvenet will turn to page 111 of the second edition of F. W. Clarke's monograph, "The Data of Geochemistry," he will find the following: "The fact that sea water contains gold was first established by E. Sonstadt in 1872 [Chem. News, 25, 196, 231, 241, (1872); 74, 316 (1896); Am. Chemist, 3, 206, (1872)]. Its presence has since repeatedly been verified. In 1892 C. A. Munster [Jour. Soc. Chem. Ind., 11, 351, (1892) From Norck Tekn. Tidsskr.] examined water from the Kristiania Fjord, Norway, and found in it 5 to 6 milligrams of gold, with 19 to 20 of silver, per ton. In each analysis he used 100 liters of water. Liversidge [Proc. Roy. Soc. New So. Wales, 29, 335, 350 (1895)] found the gold in Australian waters to range from 0.5 to 1.0 grain per ton. At either rate, gold is present in the ocean in thousands of millions of tons. Liversidge [Jour. Chem. Soc., 71, 208 (1897)] also detected gold in kelp, rock salt, and a number of saline minerals, such as sylvine, kainite, carnallite and Chilean niter. In one sample of kelp he found 22 grains of gold per ton, and in a bittern, 5.08 grains. J. R. Don [Trans. Am. Inst. Min. Eng., 27, 615 (1897)] examined both ocean water and oceanic sediments. In the former he detected 0.071 grain of gold per metric ton, but the sediments were barren. In waters collected near the Bay of San Francisco, Wagoner [Trans. Am. Inst. Min. Eng., 31, 806 (1901)] found, also per metric ton, 11.1 milligrams of gold and 160.5 of silver. In deep sea dredgings Wagoner detected even larger quantities of both precious metals. [Trans. Am. Inst. Min. Eng., 38, 704 (1907)]. P. DeWilde [Arch. Sci. Phys. Nat., (IV), 79, 550 (1905)] and

A. Wiesler [Zeitschr. angew. Chem., p. 1795 (1906)] have published good summaries relative to the detection of gold in sea water, and also discussed the possibility of its economic recovery."

It appears then, that the trail that "ran up a tree" has run down again on the other side.

Electric Zinc Smelting

To the Editor of the Metallurgical and Chemical Engineering:

SIR: In the August issue of METALLURGICAL AND CHEMICAL ENGINEERING a letter is published from Mr. F. L. Clerc commenting upon my article which appeared in the issue of November, 1912, entitled "Causes of the Practical Non-success of Electric Furnaces in Treating Zinc Ores."

Although my poor knowledge of English compels me to avail myself of translators who are liable to alter sometimes the meaning of what I intend to convey, I doubt whether I have put my name to an article in which it is stated that the production of carbonic acid in the actual electric furnaces is approximately equal to that of the retorts employed in the ordinary process.

On the contrary I have said (this journal, Vol. X, page 747): "This fact of the production of blue powder which does not take place in the ordinary retorts, or, if it does, in very small quantities, is due to the formation in the electric furnaces of a much higher percentage of carbon dioxide than in the usual retorts."

While I do not share all of Mr. Clerc's view, I agree with him as far as the influence of the cooling of zinc vapors, on the production of blue powder, is concerned. It is uncontested and a recognized fact that a too rapid or too intense cooling of these vapors gives rise to an excessive and sometimes total production of blue powder.

It is, in fact, this phenomenon which occurs in the electric furnaces when they are started, when care has not been taken to heat the condensers beforehand to the required temperature.

In such a case the phenomenon is even increased by the direct oxidation of the zinc vapors caused by the air contained in the condensers at the moment when it is set working.

The role played by the temperature in the condensation of the zinc vapors is well known to me and if I did not refer to it in the article on which Mr. Clerc comments it is that I considered this feature irrelevant to the subject I proposed to deal with.

In my article, in fact, I only intended to consider the present electric furnaces, their working and the manner in which they bring about the reduction of zinc ores. I left aside the condensation of the zinc which, after all, is only an accessory operation, very important no doubt, but which can and must be done easily if all necessary precautions are taken and if the reactions which release the zinc have been effected normally and without oxidation inside the furnace.

These indispensable precautions are principally the maintenance of the condensers at a temperature superior to that of the solidification of zinc (the most convenient appearing to be between 600° and 700° C.), and, as much as possible, the separation of the zinc vapors from other gases evolved by the reduction.

After this digression on the condensation problem, I regret to say that I am not at all of the opinion of Mr. Clerc as far as the reduction of zinc ores in electric furnaces is concerned.

Mr. Clerc seems to consider as a fairy tale the fact that the actual types supply a considerable proportion of blue powder. This is nevertheless so and all those who have experimented with electric furnaces agree in admitting that this notable proportion is produced, whatever thermal precautions may be taken to condense the zinc.

Mr. Clerc attributes the oxidation of zinc vapors in electric

furnaces solely to the presence of air entering the furnace by the open space around the electrodes. I also thought so previously, but having made experiments with a furnace in which this defect was eliminated I convinced myself that the oxidation was not due solely to the incriminated cause.

In the furnace I used (patent No. 989,169) the movable electrodes were fixed at the extremity of a round iron rod, which went through the furnace walls in an airtight joint in order to prevent absolutely the entrance of air. Notwithstanding said precaution, quite a notable amount of oxidation of zinc vapors took place, though of course in a lesser proportion than when ordinary electrodes are employed.

This led me to the conclusion that the proper working of the electric furnace was defective in itself and brought me to investigate the nature of the defects and their causes.

My investigations have been based on the following remarks: With arrangements as actually used, coal dust is found

Though Mr. Clerc is of the opinion that such an improvement is of difficult realization, it appears to me that the aim has been attained in the furnace hereunder described and shown by the attached drawings (Figs. 1 to 3).

This furnace, as indicated, is operated by three-phase currents, but may be adapted to the use of two-phase or single-phase current or of direct current. It is made up as follows:

A, heating and charging chamber.

B, reduction chamber separated from A by partition P, which is provided with a central opening.

C, crucible chamber.

E E, set of shunted electrodes which can be connected, one apart, by interruptors J with phase I of the electric current.

E' E', set of shunted electrodes which can be connected by interruptors J with phase 2.

The electrodes E and E' are not plunged in the charge, but simply placed in contact with it. The open space between the walls and the electrodes is filled up by an appropriate luting.

S, sole connected with phase 3.

J, interruptors to put in circuit, at will, the lateral electrodes E E'.

L, spout to draw the slag.

M, spout to draw the metals which are not volatile (lead, copper, etc.).

O, openings for the escape of gas and vapors.

R R', lateral chambers, their object being to facilitate the condensation: First, by separating by different densities the zinc vapors from the reduction gases; second, by lowering the temperature of the zinc vapors to an intermediary degree between that of production and that of condensation.

P G, partition and angle iron destined to facilitate the escape of the gases and vapors.

H, pipe leading the zinc vapors into condensers maintained at a temperature of 600-700° C.

It is easy to convince oneself that the whole charge contained in the reduction chamber B of this type of furnace is crossed in all directions by the electric current and that all of said charge is maintained practically at a uniform temperature. This is regulated as required by means of the interruptors J which modify the number or the position of the electrodes put in circuit.

The experiments carried out with a furnace of this type gave excellent results in every respect: thermic efficiency, yields of metal, etc., the production of blue powder being 2 per cent, more or less.

If it is taken into account that this furnace eliminates the very defects which I pointed out as the causes of the bad working of the actual electric furnaces, it remains evident that the remarkable results obtained are the best arguments in favor of my assertions.

It is besides evident, at first sight, that the reduction should not be performed as quickly as possible, and that the minimum duration is limited by the obligation to obtain absolutely complete reactions. The experimental results are unanimous in demonstrating this fact. It is sufficient, in fact, in an electric furnace working under normal conditions to increase the density of the current to notice at once an increase in the proportion of the blue powder produced.

Mr. Clerc seems to admit that this excessive speed is advantageous because it reduces the losses in radiation and facilitates the condensation.

I am at a loss to see why the condensation should be rendered easier. On the contrary, it would seem that the production of too rapid reactions necessarily gives rise to the passage into the condensers, where their presence is pernicious, of all the gases resulting from these reactions.

As regards the profit realized by the losses in radiation, this is entirely imaginary. For this gain would be more than absorbed by the losses resulting therefrom, such as defective working, bad returns in metal, etc. Besides, even taking into account the losses only in radiation, I figure that on the basis of equal production, those of the ordinary electric types would

FIGS. 1 TO 3.—SECTIONS OF ELECTRIC ZINC SMELTING FURNACE.

even in the condensers, this could only be brought about by a strong outrush of gas and vapors which is caused by a too rapid reduction, and this in turn is the result of too high a temperature in a too limited space; there is inevitably an insufficient contact of the bodies in presence of one another. Therefore the reactions that should have existed between these bodies only take place in a very imperfect manner, and I was led to the conclusion that the defect stated was due, more particularly, to the great rapidity of the reduction and that to remedy the same it was necessary to provide the furnace with some means of considerably increasing the capacity of the active zone of reduction, while maintaining a moderate but sufficient temperature and as even as possible.

be at least equal, if not superior, to those of the above described furnace.

In conclusion, therefore, and notwithstanding the apparent value of Mr. Clerc's arguments, I consider myself justified in considering as correct the opinions given in my last article, not only because I consider them based on logical arguments, but more particularly because they are supported by practical experimental results.

These results can be verified by any one interested in doing so and it will afford me pleasure to furnish parties desirous of making new experiments, with a furnace of the described type, and all information they may like to solicit from me.

Like any discussion, it is to be hoped that this one will tend to bring some light on the electric treatment of zinc ores, and if such result is obtained it will be fair to give the credit to Mr. Clerc for the large share he took in it.

Mexico City, Mexico.

The Western Metallurgical Field

Minerals Separation Flotation in Colorado

The first use of the Minerals Separation flotation process in Colorado is now under way at two places in the state, on two different classes of material. Earlier attempts have been made to introduce flotation processes in Colorado, but without success; the ores were not amenable to the methods used, and the ventures seem now to have been ill-advised. It appears, however, that the Minerals Separation process is to be successful, as the first results obtained are promising, and further familiarity with the process will enable its operators to improve their work.

One of the flotation machines is at work at Leadville, on the re-treatment of an old zinc tailings dump. This material has been tested before by various concentration processes, but has resisted successful treatment. It requires grinding to liberate the zinc mineral and the difficulty of saving this fine mineral has proved a stumbling block. The Minerals Separation process, however, is adapted to the recovery of finely divided mineral and is apparently proving successful. It is possible that some coarse concentration can be done, but most of the ore has to be tube-milled before treatment.

The other application of flotation is at Ouray, where original mine ore is being treated. The material is a mixed sulphide, containing pyrite, blende, galena and silver. The minerals are brittle and entailed heavy losses in ordinary wet dressing. The first work was done on fine pulp classified from the stamp-mill product, the coarse being treated on tables as before. It is understood that the flotation machine was successful in handling this product, and that the final design of the concentrating system is now under way. The product of flotation probably will be a mixed sulphide concentrate, requiring further separation, but as there is an electrostatic separating mill at Ouray, the flotation concentrate can be handled satisfactorily.

In connection with the fine grinding required in some instances to secure liberation of the mineral, the question of smelting finely divided zinc concentrate arises. Zinc smelters do not desire an undue proportion of fine concentrate, and in some cases exact a penalty based on a screen analysis of the material. But if the use of flotation brings an increasing quantity of fine zinc concentrate into the market, the smelter may find means of handling the material satisfactorily. The lead smelter has met a similar problem in blast furnace smelting by the use of the sintering machine, and possibly the zinc smelter also will be able to adapt himself to changes in zinc concentration.

Chloridizing Base-Metal Ores in Utah

Within the past year two announcements have been made concerning the use of chloridizing processes in Utah, but no technical or operating details have been made public. Interest has attached to these ventures on account of the fact that successful operators had given them approval to the extent of building plants for their application. One of these plants is

at Park City, erected for the treatment of Ontario ore; the other is in course of construction in the Tintic district. The name of Niels C. Christensen, Jr., of Salt Lake City, has been connected with the development of the processes used at both places.

A possible hint as to the nature of the latter process is contained in specifications of a patent granted on October 7 to Mr. Christensen, in which he states that "the first 100-ton unit of a large plant is now in course of erection at Silver City, Utah, for the treatment of the ores of that district by this method." Disregarding for the time the apparatus by which the process is applied, details of which appear under Recent Metallurgical and Chemical Patents in the present issue, the steps in the proposed process are as follows:

The ore is mixed with the proper proportion of sodium chloride and pyrite, to give the chloridizing reactions, and ground to the proper fineness. It is then moistened with "mill solution," which is an approximately saturated solution of salts, NaCl, MgCl₂ and CaCl₂, and some HCl. It may be that no addition of sodium chloride to the ore will be necessary, as the saturated solution of chloride salts will carry sufficient chlorine to give the proper reaction. The per cent of solution will vary from 6 to 15 per cent. The moistened ore is then charged in a uniform layer from 3 to 18 inches thick on the revolving hearth of a furnace, where it is successively roasted, cooled and discharged. The hearth is perforated, and the ore charge is subjected to the action of hot air blown through the perforations.

The chloridized ore is then agitated with mill solution, and enough bleaching powder to dissolve the gold. The general result is that the gold is dissolved by the chlorine, the silver chloride by the other chlorides, the copper by the hydrochloric acid and the lead by the acid salt solution. This rich solution is filtered, and the residue properly washed, after which the metals are precipitated successively—the gold and silver on copper and copper and lead on iron.

The acid fumes from the roasting operations are recovered in a tower, being collected in some of the precipitated mill solution. Any volatilized metals also are thus recovered.

It is stated that numerous tests on different ores, both on a large and small scale, have given extractions as follows: gold, 80 to 95 per cent; silver, 80 to 96 per cent; copper, 75 to 98 per cent; lead, 80 to 90 per cent. The process appears to be a modification of the use of chlorine in extracting both base and precious metals from the same ore.

The Tariff on Ores and Metals

The passing of the Underwood tariff bill has finally shown the producers of ores and metals just what the import duties on their products will be for some time to come. With the new rates must come a period of readjustment to conditions, but it is not anticipated that any serious disturbances will result. The legal interpretation of some of the tariff items on ore must be awaited before we will know their exact meaning.

Following are some of the items of importance to western producers: Antimony, as regulus or metal, and matte containing antimony but not containing more than 10 per cent of lead, 10 per cent *ad valorem*; old rate on regulus and metal, 1½ cents per lb., and on matte 1 cent per lb. Antimony ore is on the free list, but only as to antimony content.

Copper in plates, sheets, rods, strips, pipes, and copper bottoms, etc., 5 per cent *ad valorem*. The old rate was 2½ cents per lb. Copper ore, regulus, cement, old copper fit only for remanufacture, and clippings from new copper, were placed on the free list.

Lead-bearing ores of all kinds, containing more than 3 per cent lead, 3½ cent per lb. on the contained lead. The old rate was 1½ cents per lb. Lead in bullion, pigs or bars, 25 per cent *ad valorem*; old rate 2½ cents per lb.

Zinc-bearing ores of all kinds, including calamine, 10 per cent *ad valorem* on the contained zinc. Under the old law these ores were free if containing less than 10 per cent zinc, and the rates were graduated up to 1 cent per lb. Zinc in

blocks, pigs or sheets, and zinc dust, 15 per cent *ad valorem*. Old rate, $1\frac{3}{4}$ to $1\frac{1}{2}$ cents per lb.

Nickel, its oxide, and alloys in which nickel is the constituent of chief value, in pigs, ingots, bars, rods and plates, 10 per cent *ad valorem*. The old rate was 6 cents per lb.

Quicksilver, 10 per cent *ad valorem*; old rate, 7 cents per lb.

The following are on the free list: Platinum, unmanufactured, or made into apparatus for chemical use; plumbago; tin ore or metal, provided that a duty of 4 cents per lb. shall be imposed when the United States is producing 1500 tons annually of ore or metal; tungsten-bearing ores of all kinds, the old rate being 10 per cent.

Smelter Items

Some delay has been encountered in the installation of the Hall sulphur recovery process at the Balaklala smelter of the First National Copper Company, in California, and it is unlikely that operation will begin much before the close of this year. The anticipated success of this process means much to California smelting, which has been seriously hampered by the farmers' injunctions against the operation of smelters which discharge noxious fumes. The Hall process will produce sulphur as a by-product, and thereby eliminate this element from the smelter gases.

The Washoe smelter of the Anaconda Copper Co. was closed for about ten days early in October, for the purpose of making general repairs and a clean-up of the furnace-flue connecting with the main attack. The concentrator continued in operation as usual, treating Butte second-class ores; first-class ores were sent to the smelter at Great Falls.

Recent improvements at the Garfield smelter, Utah, consist in an extension of slag-dumping area by the construction of a steel bridge over the railroad tracks north of the plant, and in the erection of a new 350-ft. stack to supplement the present one which is 300 ft. high. All reverberatory furnaces at Garfield are now equipped for oil-firing, and are reported to be running satisfactorily.

The Arizona Copper Company produced during the month of September, 900 tons of copper. The output was considerably curtailed on account of the unexpected delay in getting the new furnaces in working order.

Goldfield Consolidated

The final report of this company's operations in August, 1913, shows that the total production was 32,096 tons of ore, the net realization from which was \$198,784. The cost per ton of ore treated was as follows: Transportation, \$0.07; milling, \$1.85; marketing, \$0.05; general expense, \$0.03; construction, \$0.01; total, \$2.01.

The Non-Ferrous Metal Market

Dullness generally characterized the non-ferrous metal market in October. Demand has been light in spite of the tendency of producers to offer metal at lower prices. The copper producers are about the only ones to maintain asking prices in the face of no business, but the statistical position of that metal is such that buyers probably will come to sellers' terms.

Copper.—The situation in Lake copper remains unchanged and the quotations are practically nominal. Little business is being done, but producers seem content to await resumption of buying. Lake copper is quoted nominally at $16\frac{1}{4}$ to 17 cents; electrolytic at 16 to 16.10 cents.

Tin.—The domestic market has been dull and reduced prices have failed to stimulate buying. The London market also has shown a steady decline. October tin is quoted at 40 $\frac{3}{4}$ cents.

Lead.—This market has declined steadily throughout the month, following the action of the American Smelting & Refining Co. on October 1 in reducing its quotations. The last available quotations are 4.25 to 4.30 cents, St. Louis, and 4.40 to 4.45 cents, New York.

Spelter.—Toward the end of the month the concessions offered by sellers had the effect of stimulating some business

in this market, but the buying was not heavy. There is, however, a stronger undertone and a more hopeful feeling. St. Louis spelter is quoted at 5.10 to 5.15 cents, and New York at 5.25 to 5.30 cents.

Other Metals.—The Aluminium market has been dull and prices are slightly lower at 20 to 20 $\frac{1}{2}$ cents, New York. Antimony has been fairly active, with prices ranging from 6 $\frac{3}{4}$ to 7.70 cents per pound. Quicksilver prices also are slightly lower, with a fair business transacted. New York and San Francisco quotations are the same, \$38 per 75-lb. flask.

The Iron and Steel Market

October, usually a month of heavy buying, and of particularly large production through favorable weather conditions, failed entirely to live up to the precedents, as it witnessed a further decrease in buying, a more pronounced decline in prices and a diminished output of steel.

By the beginning of October a majority of the mills had reached a point at which the filling of old orders could not supplement the new orders currently received so as to maintain full production. The mills caught up with their orders and became able to ship on new orders and specifications within a few days. More strenuous competition for new business naturally resulted, with more active price cutting. A concrete evidence of the eagerness of the mills for business, even in very small orders is the fact that orders given to jobbers and to the distributing warehouses of certain mills, greatly decreased, because the buyers could purchase for direct shipment at regular mill prices.

Enough has now been developed to show clearly that the new tariff of October 4, 1913, is not directly the chief influence in the price decline. In few if any instances have mills lowered prices because the buyer put them in direct competition with foreign material. Prices are declining chiefly through the domestic mills being in competition with each other. One clear indication of this fact is that the price declines are as pronounced in the central west, which is altogether immune from foreign competition, as along the Atlantic seaboard, which is "exposed." To mention one commodity, the Pittsburgh and Philadelphia billet markets have always been independent of each other and the present experience is that billets have declined at least as much at Pittsburgh as at Philadelphia.

It is possible, however, that in a general way the tariff is responsible for decreased business activity in general, resulting in a smaller volume of demand, which in its turn causes a weakening in prices, so that indirectly the tariff is responsible for the present state of the steel market. The point to be emphasized is that at the moment there is not in progress a readjustment of prices with the cost of foreign material as the moving influence. Such buying as occurs is almost wholly for immediate shipment of small tonnages, involving orders that could not be placed abroad were the price ever so attractive. As the present readjustment proceeds a price level will probably be developed at which even large orders for extended delivery could not be placed abroad with advantage, except possibly in the case of a few commodities and in a few localities, to which foreign freights are low and freights from Pittsburgh are high.

On the basis of full rated capacity, which naturally can only be attained occasionally, under exceptionally favorable conditions, steel output has been approximately as follows: In the first half of the year, 95 to 100 per cent; in July, August and September, 90 to 95 per cent; on October 1, 90 per cent; on November 1, 80 per cent. A drop to 75 per cent by the end of November is far from improbable.

Opinions vary as to the probable duration of the present lull. The most hopeful view to be found is that a definite improvement will occur in three months, or by the beginning of February, while estimates run up to nine months. A factor to which the less hopeful probably do not give sufficient weight is that the country's steel-making capacity is relatively small considering the growth of domestic demand and the export trade. Additions to

capacity have been small in the past four years and very little new construction is now in progress. In previous depressions the common thought has been that time must be allowed for demand to catch up with capacity, but to-day no one can assert that there is an excess of capacity over normal requirements. Apart from all other considerations, the remarkable manner in which the mills were able to maintain substantially full production up to October 1, in face of extreme pessimism on the part of buyers and declining business activity generally, is evidence that the trade will pick up with unusual quickness.

Pig Iron.

Our review of a month ago noted that the fore part of September had shown a slight advancing tendency in pig iron prices, the latter part of the month showing a stagnant and stationary market. In October the condition developed into a definite declining tendency. Actual declines were confined to the Philadelphia and Valley markets, Buffalo, Cleveland and Chicago showing no change, while the southern market certainly lost tone even though it did not openly decline. During the first six months of the year pig iron declined, and by an average altogether of about \$3.00 a ton, and while the advance to October 1 did not average much more than 25 cents a ton enough occurred to show that a definite upturn had commenced. This movement has had to yield to the generally unfavorable conditions, and particularly the declining tendency in steel products. The turnover in October was very light. Buyers' yards are bare and they have relatively little iron due on contract, while the merchant production has been greatly restricted and it is practically impossible for any important decline to occur. The market stands as follows: No. 2 foundry, f.o.b. Birmingham, \$11.50; No. 2X, delivered Philadelphia, \$15.75; No. 2X, f.o.b. Buffalo furnaces, \$14; No. 2 foundry, delivered Cleveland, \$14.75; No. 2 foundry, f.o.b. Chicago furnaces, \$15; at valley furnaces (60 cents higher delivered Pittsburgh) Bessemer, \$15.00; basic, \$14; malleable, \$14; No. 2 foundry, \$13.75; forge, \$13.50. Ferromanganese is \$50. Baltimore, for prompt or forward, the price fixed by the English pool. German is sometimes offered at 50 cents less, but buyers frequently take the English material despite such a differential.

Steel.

As consumption of billets and sheet bars has decreased the ordinary contracts of consumers would easily cover their requirements, furnishing no occasion for much inquiry in the open market. As mills would sell at lower prices, however, each producer having a contract must protect it by adjusting the contract price or suffer the buyer to go elsewhere. The condition has led to wholesale readjustments, but as such readjustments can be made very quietly it is difficult to determine just what has been done, and the market can be quoted only approximately. It is quite certain that a fairly good buyer would not have to pay more than \$22.50 for billets, \$23 for sheet bars or \$26 for rods, f.o.b. maker's mill, Pittsburgh or Youngstown, for either Bessemer or open-hearth. These quotations average about \$1.50 below the nominal quotations mentioned a month ago.

Finished Steel.

In nearly all products the market has been a wide open one for several months, with prices on any given date varying according to the attractiveness of the order. During October the ordinary market has declined \$2 a ton on tin plates, structural shapes and plates, and \$1 a ton on wire products and sheets. Bars have not openly declined, but the old quotation of 1.40 cents is obviously only nominal in the circumstances. The average decline of all finished steel products from the top point is now fully \$2 a ton. Ordinary open quotations, subject to shading in most cases, are as follows, f.o.b. Pittsburgh, unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill except Colorado.

Plates, tank quality, 1.30 cents.

Shapes, 1.35 cents.

Steel bars, 1.40 cents, base.

Iron bars, 1.55 cents, Pittsburgh; 1.25 cents, f.o.b. eastern Pennsylvania mill; 1.32½ cents, delivered Philadelphia; 1.20 cents, Chicago.

Wire nails, \$1.60, base; plain wire, 1.40 cents, base.

Sheets, blue annealed, 10 gage, 1.50 cents; black, 28 gage, 2.00 cents; galvanized, 28 gage, 3.05 cents; painted corrugated, 28 gage, 2.20 cents; galvanized corrugated, 28 gage, 3.10 cents.

Merchant steel pipe, 80 per cent off list for ¼ to 3-in. Steel boiler tubes, ¾ to 4½-in., 60 per cent off list.

Standard railroad spikes, 1.65 cents, Pittsburgh; 1.70 cents, Chicago.

Button head structural rivets, 1.85 cents.

Cone head boiler rivets, 1.95 cents.

Cold rolled shafting, 62 per cent off list, delivered.

Analyses of Anodes, Electrolyte, Wire Bar and Electrolytic Slime at the Great Falls Electrolytic Copper Refinery

In our September issue, p. 509, we gave an extended abstract of Mr. Willis T. Burns' excellent paper on the Great Falls Electrolytic Copper Refinery, presented at the Montana meeting of the American Institute of Mining Engineers.

To supplement the information given in our September issue, we give here the table of complete analyses of anodes, electrolyte, wire bar, and electrolytic slime, from Mr. Burns' paper. This table will be found exceedingly interesting, both by itself and in connection with the article in our September issue.

	Converter Anodes Per Cent	Electrolyte Per Cent	Wire Bar Per Cent	Electrolytic Slime Per Cent
Copper	99.1300	3.280	99.9500	43.3400
Arsenic	0.1183	0.500	0.0016	3.0300
Antimony	0.0534	0.041	0.0015	3.4600

New York Section of the American Chemical Society

The first meeting of the season of the New York section of the American Chemical Society was held in the Chemists' Building on October 10th.

The chairman of the section, Dr. B. C. Hesse, in his opening address, spoke with much common sense of possibilities of changing the method of presentation of papers at section meetings so as to elicit more lively discussion. Professor F. J. Pond presented then a long paper giving a historical review of the pioneer work on the synthesis of rubber which was discussed by various speakers.

Joint Meeting on Metallurgy of Zinc

A joint meeting of the New York Sections of the American Institute of Mining Engineers and of the American Electrochemical Society will be held at the Engineering Societies' Building, 20 West 30th St., New York City, on Thursday, November 20, 1913, at 8:30 P. M. The subject of the evening is the metallurgy of zinc, and the following papers will be presented:

Progress in the Metallurgy of Zinc. By George C. Stone.

Electric Smelting of Zinc Ore. By W. R. Ingalls.

Electrolytic Refining of Zinc. By Victor Engelhardt.

"Following these papers there will be a joint discussion of the subject. As there is much conflicting opinion on the future of zinc, it is expected that there will be much disorder."

Foundrymen's Convention and American Institute of Metals

Report of Chicago Convention

The annual conventions of the American Foundrymen's Association and of the American Institute of Metals were held in Chicago from October 14 to 17.

Mr. Alfred E. Howell, Nashville, Tenn., is the vice-president of the American Foundrymen's Association; Dr. Richard Moldenke, Watchung, N. J., was reelected secretary-treasurer.

The vice-presidents elected are: Messrs. R. A. Bull, H. A. Carpenter, S. B. Chadsey, G. R. Lombard, T. L. Richmond, T. W. Sheriff, J. J. Wilson, and Walter Wood.

At the last session a silver-loving cup and salver was presented to Past President Seaman, the first president of the Association and president of the Seaman-Sleeth Company, of Pittsburgh.

The banquet was attended by more than 300 men. There was no speech-making, but music and a cabaret and much gaiety.

The exhibition of foundry equipment and machine tools again proved very attractive and was well attended.

Among the papers presented in the technical session were papers by W. S. Quigley on the use of powdered coal as fuel by F. T. Snyder on electric steel castings, by R. A. Bull on some difficulties in pouring steel castings, by E. L. Leasman on the annealing process for malleable castings by W. S. Hoyt on oxy-acetylene welding and cutting.

Notices and abstracts of some of them are reserved for a later issue.

American Institute of Metals

The Tuesday afternoon session of the American Institute of Metals was held jointly with the American Foundrymen's Association and was devoted to the presentation of a paper by Mr. M. W. Alexander on "an apprenticeship system in the metal industries," and a paper by Mr. C. E. Knoepfel on "how to make a time study."

APPRENTICESHIP SYSTEM

Mr. M. W. Alexander gave a very interesting outline of the scope and arrangement of the trade apprenticeship system of the General Electric Company and showed stereopticon views of the work done at Lynn, Mass.

The paper proved inspiring and was received with great interest. There is a general complaint of the difficulty of getting boys of any natural ability to enter the foundry trade. The need of an apprenticeship system for the metal industries is acknowledged to be very great.

HOW TO MAKE A TIME STUDY

Mr. C. E. Knoepfel, in the introduction of his paper, emphasized that the making of a time study is a most essential factor in any scheme of efficient management, and gave illustrations of the possibilities. The subject was then discussed under the following headings: Why time study is necessary; analysis of industry; the elements to be covered; variables of the man and the work; necessity for considering all factors; functions of time studies; tools needed; methods of making; studies as to classes; determining a fair standard; standardizing an operation; separation of inefficiency; detailed studies; making more than one study at a time; using regular watch with stop watch; correcting for errors; rest and fatigue; speeding the workers; practical uses of time study data; analysis sheet and schedule; organizing the work.

On account of the late hour, there was no discussion. That it was not on account of lack of interest, was proven by the Thursday session.

The attendance at this first meeting was somewhat disappointing. Both papers should have deserved a far larger audience. But many were kept away from the meeting proper by the exhibition and a desire to see men attending it.

REPORTS

The Wednesday session was opened by the presentation of the report of the official chemist, the report of the Bureau of Mines, and the report of the Bureau of Standards.

The report of the official chemists of the American Institute of Metals (Arthur D. Little, Inc.) was presented by Mr. C. F. Woods gave a concise review of the literature on metals and alloys, published during the past year. There was little discussion.

The report on the cooperative work of the Bureau of Mines with the American Institute of Metals was presented by Dr. Chas. L. Parsons. This comprises for the present the following four studies:

1. A comparative study of brass furnaces with particular reference to fuel efficiency and losses of metal in melting.
2. Study of the precautions to be taken for health and safety in the brass foundry.
3. The development of a suitable pyrometer for molten brass.
4. The development of an electric furnace for brass melting.

H. W. Gillett has completed an extensive investigation of problems 1 and 2 and his comprehensive report is to be published shortly in bulletin form. Work is going on with two promising types of electric furnaces for brass melting.

The discussion showed a vastly increased interest in the use of the electric furnace for brass and bronze. Mr. Wallace, of the National Cash Register Company, emphasized the crying need of a pyrometer for use in molten brass—that is, a works tool, not merely a laboratory instrument.

The report on the cooperative work of the Bureau of Standards with the American Institute of Metals was presented by Mr. G. H. Clamer. This work is on test bars and the report gives a discussion of the results obtained to date at the Pittsburgh branch of the Bureau of Standards on gun metal, various forms of test bars, cast in green and dry sand, flat and upright, with and without shrink heads and at different pouring temperatures. The rate of cooling has a great effect. A remarkable sag in the pouring temperature-tensile strength curve is reported at a pouring temperature of 1150 to 1160 deg. C.

INTERNAL STRAINS

A paper by Mr. J. E. Howard reported on the magnitude of internal strains set up in brass, copper, etc., by peening the surface or bending. Strains as high as 15,000 lb. per square inch were reported. Further the release of all or part of the strains by annealing was shown. All this work was done on rolled bars, as preliminary to the projected work on strains in castings.

BUREAU OF STANDARDS

A paper by Dr. G. K. Burgess on "the work in metals at the Bureau of Standards," was made quite interesting by some forty lantern slides of apparatus shown.

One of the most important functions of the metallurgical division will be the preparation of standard chemical samples, metals and ores, to secure a uniform product not only for chemical standards, but also for pyrometric and metallographic purposes.

Regarding the work on non-ferrous standard chemical samples, the chief chemist of the Bureau, Dr. W. F. Hillebrand, was quoted as follows:

"The Bureau will soon issue a rolled brass carefully analyzed like its iron, steels and ores, for the purpose of checking analysis and their analytical methods. The preparation of a cast brass is also contemplated and, in fact, a sample was prepared and nearly ready for analysis, when it was inadvertently spoiled in the process of mixing. This unfortunate accident emphasized most strongly one of the difficulties encountered in the preparation of satisfactory samples of materials of the nature of this particular brass and of all others that are subject to segregation in the casting. This brass, containing 5 per cent of lead, became very dark colored during the operation of mixing in the machine specially designed for the purpose of mixing metal chips, and it was found that the lead alone seemed to have undergone marked oxidation. The sample had to be discarded and will not be replaced until some method of casting is devised that will insure the requisite homogeneity without mixing. Possibly the method of comminuting directly from the molten mass, as is successfully employed for solders and

other similar alloys, can be applied to brasses also, but thus far success does not seem to have been attained."

"The experience already gained at the Bureau shows clearly how extremely difficult it is to secure perfectly homogeneous samples of several hundred pounds weight and also how difficult it is for co-operating analysts to obtain agreeing analyses of samples that are homogeneous. I would emphasize in this connection the futility of sending out for co-operative analysis test samples which are not known positively to be entirely homogeneous, or at least sufficiently so to justify the expectation that the results obtained by different analysts will really furnish a true criterion either of the skill of the several analysts or of the reliability of the methods used by them. Before they are sent out for such comparative test by different analysts, the precaution should be taken to have each sample carefully analyzed by one competent man and by the same method, in order to ascertain if they all represent material that is really of the same composition."

"Given a material of satisfactory character there remains the fact, shown clearly by the experience gained at the Bureau during the past few years, that the art of analysis is yet far from being established on a satisfactory basis. Analyses by supposedly very competent men often vary widely. It has become evident that this disagreement is often due to lack of knowledge of the limitations of the method used or to disregard of minor, yet important, details in the analytical procedures that apparently can be overcome only by a closer study of some of the analysts of the errors that are often involved in their methods, errors of which they are seemingly unaware, or which they are inclined to disregard as unimportant. Often they are unimportant from the point of view of ordinary industrial needs, but the fact remains that when it is necessary to determine the composition with a high degree of accuracy, the analysts are too often unable to or do not apply the refinements that are necessary for the attainment of really precise results. It seems hopeless to expect great improvement in this respect by leaving the methods of procedure to the judgment of each analyst, hence arises the need for a very careful study of the comparative value of different analytical methods for a given material and of the most precise specification of the entire procedure to be followed for the method or methods that shall be found most suitable."

THE NOMENCLATURE OF NON-FERROUS ALLOYS

A second paper, by Dr. **G. K. Burgess**, of the Bureau of Standards, emphasized the need of a systematic nomenclature of non-ferrous alloys. Tentative suggestions were made as to the system. Nothing final, however, is to be done until the matter has been thoroughly gone into by the Bureau of Standards in cooperation with committees from various societies.

The discussion showed not only the willingness but the desire of the membership at large to reform the nomenclature in a rational way.

BRASS FOUNDRY OF THE FUTURE

This was the subject of the last paper on the program for the Wednesday session, by Mr. **C. P. Kerr**, of the Bureau of Standards.

The trend of his paper is indicated by the concluding remarks:

"The success of the brass foundry of the future will depend more upon the training of the man in physical and metallurgical science and his ability to apply his knowledge, than upon the machinery employed, desirable though it may be as an accessory to facilitate the production of his castings. In other words, the greatest possible factor for success lies in the development of the man himself."

SCIENTIFIC MANAGEMENT IN THE FOUNDRY

While the attendance had been better at the Wednesday meeting than on Tuesday, it was best of all on Thursday, showing the broad interest of the members in the subject of scientific management.

Four papers on this subject were presented and elicited much discussion proving that the brass founders present are making much more rapid advance in scientific management than is gen-

erally thought. Not a single word of opposition to scientific management was heard. All seemed agreed as to the desirability of standardizing conditions, planning and dispatching, of time and motion study and of some form of efficiency rewards by which the worker is allowed to make as high wages as he can without fear of a cut in wages, the price having been scientifically set by time study.

The discussion centered on the best ways of making workmen realize that the management would not cut the wages, and on the best wage system to award efficiency.

The discussion brought out in this session was considered to be so important that it was voted that it should be edited into coherent form and printed as a pamphlet in a sufficient number of copies to allow sending it to all interested, whether new members of the American Institute of Metals or not, on application to the secretary. Mr. W. M. Corse, Lumen Bearing Company, Buffalo, N. Y.

The four papers which elicited this spirited discussion were the following:

The Efficiency Engineer in the Foundry, by **E. A. Barnes**.

Preparation for Scientific Management in our Plant, by **W. M. Corse**.

How Scientific Management Works in our Plant, by **C. B. Bohn**.

Core Room Efficiencies, by **O. F. Flumerfelt**.

The discussion of the last paper mentioned showed increased interest in handling this generally neglected branch of foundry work on a scientific basis.

BOILING OF METALS

A paper on this subject by Prof. **Joseph W. Richards**, of Lehigh University, was the first on the program of the last session, held on Friday.

The author compared the evaporation of metals with the evaporation of water. He gave a very simple relation between the vapor tension curves of water and mercury. This is that mercury always boils at 1.7 times as high an absolute temperature as water, when they are boiling at the same pressure, whatever that pressure may be.

A general application of the same principle to other metals is suggested. This is possible if one definite point on the vapor tension curve of another metal is known, that is, one temperature for which we know accurately the metal's vapor tension.

"When we are told, for instance, that zinc boils at 930 deg. C. (1203 deg. A.), at normal atmospheric pressure, and we know that mercury boils at the same pressure at 357 deg. C. (630 deg. A.), then we say that the ratio of their absolute boiling points for equal pressures is $1203 \div 630 = 1.91$, and we use this ratio to construct the whole vapor tension curve of zinc from the known vapor tension curve of mercury. Or, we could equally construct it from the vapor tension curve of water, using the constant temperature ratio $1203 \div 373 = 3.2$; it seems preferable to build on the mercury tension curve, because mercury is a metal, like zinc, and we feel a little more certain of our analogy when we compare the two metals."

The author also describes how to calculate the weight of metal vapor occupying a given volume at a given temperature.

PRODUCER GAS FOR BRASS MELTING

A long paper on "the application of producer gas to brass foundries," by Mr. **E. F. Bulmahn**, was next presented.

The following description of the equipment of the Langsenkamp-Wheeler brass plant, given at the end of the paper, is interesting.

Mr. Bulmahn's paper elicited considerable discussion. Five experiments now running in a yellow brass rolling mill indicate that producer-gas-fired furnaces give lower melting cost than coal or coke, but the metal losses are not reduced.

Rolling mill men present stated that they went through the producer gas game without success and are now looking to the electric furnace, since the mill conditions require an electric power plant anyhow and the added load comes cheaper. The reduction of the metal losses is the main point in favor of the electric furnace.

COMMERCIAL OPERATION OF THE HERING ELECTRIC FURNACE

Considerable discussion was also elicited by Mr. G. H. Clamer's paper on the Hering electric furnace (pinch effect furnace) in use in non-ferrous metallurgy.

The experience with a 20 to 30-kw. experimental furnace showed that about nine pounds of yellow brass are melted with one kilowatt hour. A large furnace is being erected which is expected to increase this figure to ten.

The power factor of the small furnace is 95 per cent, that of the large one 85 per cent or better.

During the development period much transformer trouble was experienced.

A new design of water-cooled electrodes is expected to minimize electrode troubles.

No difficulty is experienced in melting copper as well as brass, even though the resistance of copper is so much lower.

Three large Hering furnaces for brass melting are in course of construction.

SILVER PLATING AND SPOTTING-OUT

A paper by Professor C. F. Burgess and Mr. L. T. Richardson, of the Northern Chemical Engineering Laboratories, of Madison, Wis., deals with the trouble of "spotting-out" in silver plating. Attention is called to the fact that while potassium cyanide was formerly used almost universally by platers, sodium cyanide has been very generally substituted for it during recent years.

The authors produce evidence which is significant in that it suggests "a difference in properties as between potassium and sodium cyanides. The statements appearing frequently in the literature that sodium salts are less deliquescent than the potassium, and will for this reason cause less spotting-out, are evidently misleading.

"There is no doubt that the spotting-out problem is of sufficient importance to warrant even more careful investigation than has thus far been devoted to it and a part of this investigation should include a study of the relative influence of the sodium and potassium cyanides. We cannot base a definite conclusion upon the mere fact that pure sodium cyanide attracts moisture more readily than does the similar potassium salt.

"It is well known that during the operation of a plating bath the cyanides are gradually converted to carbonates. These carbonates may steadily accumulate in the bath, unless removed by the use of barium cyanide as a precipitating agent. Sodium carbonate is less deliquescent than is the potassium carbonate and we thus have a factor which may argue for the superiority of the sodium cyanide."

FLUXES FOR SOLDERS

A paper by Mr. W. Arthur dealt with "soldering fluxes for soft solder" and discussed the uses, advantages, and disadvantages of zinc chloride, an ammonium phosphate solution in water, lactic acid and ammonium lactate, resin either as powder or in alcoholic solution, citric acid solution in water, and ammonium chloride for fluxing purposes.

MELTING POINTS OF COPPER-ALLOYS

"The approximate melting points of some commercial copper alloys" was the subject of the last paper on the program, the authors being Messrs. H. W. Gillett and A. B. Norton. This is an investigation of the Bureau of Mines.

The chief results are given in Table I

There was some further discussion of the Bureau of Standards report (presented on Wednesday) on test bars by Mr. Skillman.

A committee was appointed to confer with crucible makers with a view of standardizing sizes and shapes so that all makes work in all furnaces and fit all tongs. The difference in crucible sizes changes the fuel space in coke or coal furnaces and affects fuel efficiency.

The need of a practical pyrometer for brass melting became anew the subject of discussion.

NEW OFFICERS

Mr. G. H. Clamer, Ajax Metal Company, Philadelphia, Pa., is the new president of the American Institute of Metals. Mr.

TABLE I

	Composition by Analysis				Composition by Analysis				Melting Point (Liquidus) C F

W. M. Corse, Lumen Bearing Co., Buffalo, N. Y., was re-elected secretary-treasurer.

The following gentlemen were elected vice-presidents: W. H. Bassett, F. O. Clements, C. H. Ivey, Robert Job, J. L. Jones, E. Weintraub, F. Moerl, P. Mueller, C. A. Finnegan, E. S. Fretz.

Mr. H. W. Gillett, who had been in charge of arranging the very interesting program of papers for this meeting, was re-appointed chairman of the Papers Committee.

Iron and Steel Meeting of the American Institute of Mining Engineers

A very successful meeting of the American Institute of Mining Engineers was held in New York City on October 16 and 17, 1913, under the auspices of the Iron and Steel Committee. It was opened by the president of the Institute, Mr. Rand. He introduced the new chairman of the Iron and Steel Committee, Dr. Sauveur, who presided at the morning sessions of Thursday and Friday, while Dr. Richards presided on Thursday afternoon, and Dr. Raymond on Friday afternoon.

The meeting was exceedingly well attended, about 200 members being registered, and the luncheons between the morning and afternoon sessions were much enjoyed as they gave an opportunity for social intercourse.

On Friday night there was a dinner at the Engineers' Club while the Iron and Steel Committee held its dinner on Thursday night.

The morning session on Thursday was devoted to the reading and discussion of papers by W. A. Forbes on blast furnace gas cleaning; by W. H. Blauvelt on the slagging producer; by F. Peter on the generation of steam by waste heat from furnaces; by G. C. Stone on the generation of steam by waste heat from regenerative furnaces and by W. R. Shimer on over-oxidation of steel.

In the afternoon session of Thursday there was first an interesting discussion on the use of powdered coal as fuel introduced by three papers by Richard K. Meade, H. R. Barnhurst and E. W. Shinn respectively.

Then followed papers on briquetting, one by E. Stütz on the scoria process and the other one by F. A. Vogel and A. M. Tweedy on the Schumacher process, while a paper by R. H. Lee deals with the use of nodulized ore in the blast furnace. The latter paper was discussed at some length by J. E. Johnson, Jr.

The morning session of Friday was devoted to a very interesting discussion on metallographic subjects, the authors of the two main papers being Professor H. M. Howe and Dr. G. K. Burgess respectively.

The afternoon session of Friday was devoted to the discussion and reading of papers by R. R. Abbott, on the influence of various elements on the absorption of carbon by steel; by J. H. Hall on shock tests of cast steel; by G. H. Clevenger and R. Ray on the influence of copper upon the physical properties of steel; by J. H. Hall on the life of crucible steel furnaces; by H. F. Miller, Jr., on a new design of regenerators for open-hearth furnaces, and by W. E. Ruder on grain growth in silicon steel. On the whole the papers elicited an excellent discussion.

On account of limitations of space it is impossible to give a detailed report of the proceedings, but a summary of some of the more important results brought out in the various papers and discussions is reserved for our next issue.

Tests Upon the Transmission of Heat in Vacuum Evaporators.

Further Tests by Prof. E. W. Kerr

The issue of October, 1913, of the *Journal of the American Society of Mechanical Engineers*, contains a paper by Prof. E. W. Kerr, of the Louisiana State University of Baton Rouge, La., entitled "Tests Upon the Transmission of Heat in Vacuum Evaporators."

The general arrangement and the scope of the tests described in this paper are the same as described in Professor Kerr's former extensive researches, an illustrated account of which was given in our June, 1913, issue, pages 333 to 338. However, Professor Kerr's paper contains much that is new.

Tests were made with five different types of calandria. The first three types are those marked *B*, *C*, *D*, in Figs. 2 to 5 of page 334 of our June issue. The fourth and fifth types are new.

The fourth type (double-tube calandria) was built by Mr. T. F. Sanborn, of New York City, and is shown in Fig. 1. It is an evaporator of the steam-tube type with special arrangements for removing the incondensable gases.

There are two thick tube plates, one above the other, both of cast iron. The heating tubes, which are 2 in. in diameter and 54 in. long, are expanded into the upper tube plate. These tubes are closed at the top and are open at the bottom. Into the bottom tube-plate $\frac{1}{8}$ in. tubes are screwed. These small tubes are open at both ends and are placed inside of the heating tubes, reaching nearly to the top of the latter.

The space below the lower tube plate is connected to vapor space of the succeeding body in an evaporator of commercial size. Steam passes up into the heating tubes in the annular spaces surrounding the gas tubes, the incondensable gases being driven toward the top, from whence they are removed by the small gas tubes, each heating tube having its own individual incondensable gas remover. The lower tube plate is made saucer-shaped so that the condensed steam drains to the center, from where it is removed in the usual manner.

The fifth type (baffle-plate calandria) was built by Mr. A. L. Weber, of New Orleans, La., and is similar to types *B* and *C* (page 334 of June issue), with tubes $1\frac{1}{4}$ in. in diameter and 24 in. long, but differs from them in the manner of distributing

the steam to the heating tubes, and in the manner of removing the incondensable gases, the steam being supplied through four openings, one above the other, thus giving better distribution vertically. (Fig. 2 on page 612.)

Between the two tube plates a vertical baffle-plate is placed so as to guide the steam along a circuitous path to the 3-in. downtake at the center. This baffle-plate is so placed that the passage for the steam is gradually reduced in cross-section in order to keep the steam velocity as high as possible overcoming to an extent the tendency to decrease the velocity due to condensation.

The incondensable gases are drawn off by means of a small perforated pipe through the top tube plate and reaching nearly to the bottom tube plate. The object of this design is to obtain high steam velocity among the heating tubes and effective separation of incondensable gases from steam.

That part of the evaporator above the top tube plate, which is called the vapor space, was 10 ft. high in all of the calandrias tested except that of Fig. 1, in which it was about 8 ft. This liberal height was provided in order to prevent, as far as possible, the carrying over of liquid in the vapors leaving the boiling surface.

As in Professor Kerr's former tests the object was to determine the effect of the following elements on evaporation: Effect of hydrostatic head, of temperature level, of incondensable gases, of density of liquid, and of type of calandria. These will now be considered consecutively.

Effect of Hydrostatic Head

Tests were made on four different calandrias in order to secure data on the effect of hydrostatic head. The results were plotted diagrammatically and for comparison the theoretical curves were also plotted according to calculations based upon the theoretical loss of temperature due to hydrostatic head. (The method of these theoretical calculations was given on page 334 of our June issue.)

Theoretically the coefficient of heat transmission decreases with increasing height of boiling liquid above lower tube plate. The results of the tests confirm this, but in all cases the loss in heat transmission due to hydrostatic head was considerably in excess of the theoretical, and the excess was greater for short tubes than for long tubes. The loss with varying heads, other conditions being equal, varies according to a straight-line formula.

The test curves seem to indicate that with tubes having the same length the rate of decrease in evaporation due to hydrostatic head is practically constant. But the curves for the 24-in. tubes are much steeper than those for the longer tubes (48 and 54 in.) showing that the effect of hydrostatic head is greater with short tubes than with longer ones. This is difficult to explain, although circulation doubtless has something to do with it.

Effect of Temperature Level

The total temperature fall in a multiple effect may be increased by increasing the temperature, or what is the same thing, increasing the pressure of the steam supplied to the first body, or by decreasing the pressure and temperature in the vapor space of the last body. It is evident that increasing the temperature fall, and therefore the capacity, by the first method results in increasing the average temperature in the heating compartments and that the second method results in decreasing it.

The relative advantages of high steam pressure in the first body as compared with high vacuum in the last body in obtaining increased heat transmission has been a matter of some question by many. Then, too, the reason for the inequality of temperature fall in the different bodies of a multiple effect, the greatest fall being always in the last body where the temperature level is lowest, is not definitely known, although it has been thought that the lowest steam density in the last body might be partly responsible.

In order to get data that would aid in settling these points a large number of tests were made. The results are given in tables and diagrams. The chief conclusion is as follows:

FIG. 1.—TYPE E DOUBLE-TUBE CALANDRIA

Other conditions being equal, the lower "the temperature level" the smaller the coefficient of heat transmission; in other words, the lower the temperature and density of the heating steam the smaller the coefficient. The coefficient U of heat transmission varies according to the equation

$$U = 2.25 + 17,500 D,$$

where D density of heating steam in pounds per cubic foot.

Effect of Incondensable Gases on Heat Transmission

The tests on this subject gave the following result:

Air or other incondensable gases in the heating steam greatly

reduce the heat transmission, even with relatively low vacua. The coefficient of heat transmission U varies according to the equation

$$U = C (P_s/P_t)^3$$

in which C is a constant, P_s the partial pressure of the steam and P_t the total pressure. The presence of "air-pockets" may be conveniently determined by means of thermometers in the steam compartment; good circulation and distribution of steam are important in preventing them.

In the equation for the curve

$$U' = (P_s/P_t)^n$$

the exponent n has a value of nearly 3, showing only a slightly greater decrease of the coefficient due to air than in the tests by George A. Orrok (*Transact. Am. Soc. M. E.*, Vol. 34, p. 713) on the subject of air in surface condensation in which the value of 2 was given to n . The absolute pressure in the evaporation tests was about 16.5 in. of mercury, whereas in the Orrok tests it was only about 2 in. These evaporator tests differed also from the condenser tests referred to as regards hydrostatic head and the range of the values of the coefficient of heat transmission. In the Orrok tests the maximum coefficient was only slightly above 300, while in the evaporator tests it was above 500. This latter was probably due to the greater steam density in the evaporator tests.

Attention has already been called to the fact that the evaporators shown in Figs. 1 and 2 were designed for the special purpose of overcoming the bad effects of incondensable gases. While it was practically impossible to determine the amount of air present, for the reason that the temperature existing adjacent to the heating surface could not be measured, the results obtained with these two arrangements show considerable improvement in heat transmission over those obtained from the others. The increase is doubtless due mainly to the more effective separation of air from the steam and to its prompt removal from the heating compartment.

Density of the Liquid

Increasing the density of the boiling liquid causes a loss in heat transmission due to the decrease in temperature fall. As the density is increased the boiling temperature increases according to the equation $y = C D^p$, in which C = a constant and D = density in deg. Frix. The total loss due to the density of the boiling liquid seems to be in excess of that due to loss of temperature fall. This is due to lower velocity of circulation.

Last Body of a Multiple Effect

The great temperature fall required in the last body of a multiple evaporator is due to the combined influence of greater amounts of air, steam of lower density, liquid of higher density, also, in many cases, more foul heating surfaces than in preceding bodies.

Type of Calandria

The five calandrias tested differ from each other in several fundamental features. Most important among these differences

FIG. 3.—CURVES COMPARING HEAT TRANSMISSION IN DIFFERENT CALANDRIAS TESTED. CURVES 1 AND 2, CALANDRIA FIG. 1; CURVE 6, CALANDRIA FIG. 2; CURVES 3, 4, 5, CALANDRIAS B, C, D

of design may be mentioned proportions of tubes; that is, ratio of length to diameter, the use or non-use of downtakes to aid the circulation of the juice, and the methods employed for removing incondensable gases.

Comparative curves for the different calandrias are shown in Fig. 3. Curves 1 and 2 refer to the double-tube calandria shown in Fig. 1 in this article. Curves 3, 4, 5, refer to the standard types B, C, D, of calandria respectively, illustrated in our June issue, p. 334. Type C (curve 4 in Fig. 3) has a downtake, types B and D have not. Curve 6 refers to the baffle-plate calandria shown in Fig. 2 in this article.

Curves 3 and 5 show something as to the effect of varying the proportions of the tubes, the former for tubes 1½ in. by 24 in. and the latter for tubes 2 in. by 48 in., some advantage being shown for the long tubes, at least for low temperature levels. The greater heat transmission in the long tubes is probably due to better circulation. The greater the ratio of the length of a tube to its cross-sectional or carrying area, the greater will be the heat transfer per unit of carrying area, and this should increase the velocity of circulation.

A comparison of curves 3 and 4 shows a decided advantage for the downtake calandria over that without a downtake. The tests on the downtake calandria were made with a hydrostatic head of 16 in., whereas those on the other were made with a 12-in. head. Correction for this difference would slightly increase the advantage shown for the downtake calandria.

Curves 1 and 6 show the results of the tests on the two types of evaporators designed especially for efficient removal of incondensable gases. Both show coefficients of heat transmission considerably in excess of those obtained with the standard types represented by the curves 3, 4 and 5. Curve 6 for calandria of Fig. 2, the baffle-plate calandria with a head of 12 in., is only slightly higher than curve 1, which represents Fig. 1, the double-tube calandria with an 18-in. head. While the good results shown for these two calandrias may undoubtedly be attributed mainly to the more efficient separation of incondensable gases from steam and its removal, it is probable that the increased velocity of steam is also partly responsible.

FIG. 2.—BAFFLE-PLATE CALANDRIA

The Chile Copper Co. has an immense deposit of copper ore at Chuquicamata which consists mainly of brochantite, $\text{CuSO}_4 \cdot 3\text{Cu}(\text{OH})_2$. The plan for treating this ore includes crushing to ½-in. size, leaching in vats with sulphuric acid, and electrolyzing the solution. The initial unit will have a capacity of 9000 tons per day.

0.5 Watt Per Candle Tungsten Lamps

Another Triumph of Physico-Chemical Research

At the meeting of the American Institute of Electrical Engineers, held in New York City, on October 10, 1913, two papers were presented on tungsten lamps of high efficiency. The first, by **Irving Langmuir**, dealt with "blackening of tungsten lamps and methods of preventing it." The second, by **Irving Langmuir** and **J. A. Orange**, with "nitrogen-filled lamps."

Both papers were presented by Dr. Langmuir. The presentation was accompanied by a series of most interesting experiments and demonstrations. These papers are printed in full in the October number of the *Proceedings* of the American Institute of Electrical Engineers, pages 1895 and 1915 respectively. We herewith give abstracts of both papers and comment on them on the editorial pages.

Blackening of Tungsten Lamps

The efficiency at which tungsten lamps may be profitably run is limited principally by the blackening of the bulb. It has usually been considered, especially among those most experienced in lamp manufacture, that the blackening of ordinary lamps was due very largely, if not entirely, to the presence of residual gases. The evidence which has led to this belief is discussed by Dr. Langmuir.

The sources of gases with the lamp were studied in detail. The principal gases are found to be water vapor, carbon dioxide, carbon monoxide, hydrogen, nitrogen and vapors of hydrocarbons. The specific effects produced by these and other gases were carefully determined by Dr. Langmuir. It was found that water vapor is the only one that produces perceptible blackening of the bulbs. The blackening by water vapor is due to a cyclic process in which the water oxidizes the tungsten and is itself reduced to atomic hydrogen. The tungsten oxide volatilizes and deposits on the bulb, where it is reduced by the atomic hydrogen to metallic tungsten and water vapor is again formed.

Attempts to materially improve the life of well exhausted lamps by the more complete removal of water vapor resulted, however, in failure. It is therefore concluded that, although water vapor is usually the cause of the short life of poorly exhausted lamps, yet it is not the cause of blackening in well exhausted lamps.

The real cause of blackening in well made lamps was proved to be evaporation of the filament, due to its temperature alone.

In order to test evaporation of the filament as the cause of the blackening, many experiments were undertaken to determine the rate of loss of weight of tungsten filaments when run at various temperatures in lamps. It was found that in lamps with filaments run at the same temperature the loss in weight was proportional to the surface of the filament and independent of the size of the bulb. The temperature coefficient of the rate of loss of weight was extremely high, as would be expected if it were proportional to the vapor pressure of the metal.

Furthermore, the actual measurements at various temperatures agreed remarkably well with the rational formula for vapor pressure

$$\log P = A - \frac{B}{T} - C \log T$$

From some simple considerations of the kinetic theory of gases, it became possible to calculate the actual vapor pressure of tungsten at various temperatures. It is of interest to give here simply the results at a few temperatures:

Efficiency, watts per candle	Temperature, absolute	Vapor Pressure, mm.
1.0	2400 deg. K.	0.000,000,05
0.4	2800	0.000,03
0.2 (melting-point)	3540	0.080
(boiling-point)	5200	760.

After it had been definitely settled that the blackening of tungsten lamps is caused by the evaporation of the filament a method of preventing the blackening is at once indicated.

This is the provision of a chemically inert gas in the bulb, as it will tend to reduce the evaporation of the filament. Most gases react chemically with tungsten at high temperature, but hydrogen, nitrogen, argon, and mercury vapor seem to be chemically inert towards it.

Experiments showed that the evaporation of the tungsten in an atmosphere of hydrogen, nitrogen, or mercury vapor was indeed much reduced. But further experiments were necessary to determine whether the decrease in evaporation was sufficient to offset the loss of heat by convection from the filament through the inert gas.

With hydrogen the loss of heat offsets the benefit of reduced evaporation. The reason is that the heat of conductivity of hydrogen at very high temperatures is abnormally great, due to the dissociation of the hydrogen into atoms.

With nitrogen and mercury vapor it is different. The experiments indicated that the heat loss by convection increases at high temperature rather slowly with increasing temperature in the case of nitrogen and mercury vapors, though very rapidly in the case of hydrogen as stated. Further, the heat loss from very small wires, say 0.001 in. in diameter, is not very greatly different from that from wires several times this diameter. In other words, it is much more nearly correct to say that the heat loss by convection from small wires is independent of the diameter, than to say that it varies proportionately with the diameter.

Tables were worked out which showed that the loss of efficiency (at constant temperature) due to the introduction of a gas at high (atmospheric) pressure is very much greater for filaments of small size, than for the larger ones, so that with wires of the sizes ordinarily used in lamps the temperature would have to be raised excessively in order to obtain an efficiency of even one watt per candle. Thus in nitrogen a filament of 0.0021 in. diameter (the size ordinarily used in a 20-watt, 110-volt lamp) would have to run at 3000 deg. to give one watt per candle. At this temperature of filament, the life of the ordinary lamp would be about 20 minutes, or about one fifteen-hundredth as long as that when running normally at one watt per candle in vacuum.

With filaments of larger diameter (0.005 in. and more), the loss of heat by convection is not nearly so serious, so that, if the rate of evaporation of the metal is very largely reduced by the presence of the gas, it is possible to raise the efficiency considerably without shortening the life.

The advantages of a large diameter filament can be practically obtained by coiling a smaller wire into a tightly wound helix or otherwise concentrating it into a small space.

Further experiments showed that the presence of the inert gas can be utilized in another manner. Not only does the gas decrease the rate of evaporation, but by proper design the course of convection gas currents can be directed along such channels that those parts of the bulb that are to transmit the light remain perfectly clear and any blackening deposit occurs on portions of the bulb where the blackening effect is of no account.

Nitrogen-Filled Lamps

In the second paper of which Irving Langmuir and J. A. Orange are joint authors, the authors state that by making use of the above principles they have been able to construct practical tungsten lamps which, starting at an efficiency of about 0.40 watt per candle, have run over two thousand hours, the average efficiency during life being better than 0.5 watt per candle. But such a degree of improvement has been reached only in lamps taking large currents.

Early experiments indicated the desirability of using a filament of large diameter. The larger filaments gave not only a better efficiency at any definite temperature, but also a much longer life. Thus doubling the diameter increased the efficiency from 0.05 to 0.56 and increased the life from ∞ to 300 hours.

The improvement in the efficiency is due to the relatively smaller heat loss by convection from thicker wires.

The life of the filament is determined largely by the loss of tungsten from the filament by evaporation and depends on the *relative* decrease in diameter caused by this evaporation. If the rate of evaporation per unit area from large and small wires were the same, the lives of various filaments run at a given temperature would be roughly proportional to their diameters. However, as the evaporation of tungsten in nitrogen is largely a diffusion process, it probably obeys laws similar to those of conduction or convection of heat from a wire: that is, for wires of small diameter, the actual amount of tungsten evaporated would be nearly independent of the size of the wire. The rate of evaporation *per unit area* would thus be approximately inversely proportional to the diameter. The relative lives of very small wires in nitrogen are therefore nearly proportional to the squares of their diameters.

It is, however, not desirable to use filaments of very large diameter if similar results can be obtained with smaller ones.

Unless very low voltages are used, the power consumed with the larger wires is so great that only very high candle-power lamps can be made.

Therefore, it was of vital importance to increase the effective diameter of the filament without decreasing its resistance, and

increased heat loss both by convection and radiation, and thus prevent local overheating or spotting.

The use of helically wound filaments increases the life of the lamp many times beyond the life that would be obtained with a straight filament running at the same efficiency. This is especially true of the smaller sizes of wire.

The authors then discuss the principles of the design of bulbs and locations of filaments.

In ordinary lamps about 20 per cent of the energy radiated from the filament is intercepted by the glass and causes heating of the bulb. In the nitrogen lamp, beside this radiated heat, there is an additional amount of heat carried to the bulb by convection—an amount varying with the type of lamp and ranging from 6 to 40 per cent of the total input. The convection currents carrying this relatively large amount of heat travel vertically upwards from the filament and strike a relatively small area of the bulb, which thus tends to become greatly overheated. Unless special precautions are taken, this overheating will cause the liberation of enough water vapor to cause attack of the filament and consequent blackening of the bulb. It is thus highly desirable, in ordinary cases, if small bulbs are to be used, that the filament should be placed in the lower part of the bulb. This has the further advantage that it allows sufficient surface of glass in the upper part for the deposition of the tungsten nitride.

For a similar reason it is generally desirable, although not necessary, to make the bulbs with their height considerably greater than their horizontal diameter.

By special design of the bulb, satisfactory lamps have been made with bulbs of only one-half to one-third as large a volume as that of evacuated lamps of the same wattage. This means that for bulbs of the same volume the nitrogen lamps give roughly from five to ten times the candle power of evacuated lamps. The bulbs of such lamps naturally run much hotter than those of ordinary lamps. The upper parts of the bulbs are often 100 to 200 deg. C. or more, while the lower parts are sometimes much cooler than this, although closer to the filament.

A few notes are given on lead-in wires and supports and it is mentioned that platinum has been discarded entirely, even in the smaller sizes. Mostly special alloys are used which have the same coefficient of expansion as the glass. Bulbs of special glasses into which tungsten or molybdenum wire can be sealed directly have also been used.

The principal limitations of the new type of lamp is that of current. There is no practical upper limit to the current.

For the particular type of nitrogen-filled lamp which has at present been furthest developed, it may be said that a life of over 1500 hours is obtained at efficiencies better than 0.50 watt per candle only in large units taking over ten amperes. Lamps running at 0.6 to 0.7 watt per candle have been made in units taking at least 5 amp.

A number of special types of nitrogen-filled lamps have been made as follows:

(1) *Large units of very high efficiency*, consuming 0.4 to 0.5 watt per candle with a life of 1500 hours or more. These take currents of 20 to 30 amp and (except in units over 4000 cp) are, therefore, best run from alternating-current circuits by means of small transformers or auto-transformers giving a voltage depending on the size of unit desired. Thus with 30 volts and 25 amp, the power would be 750 watts and this in a lamp of 0.45 watt per candle would give 1670 candle-power. Typical lamps are shown in Figs. 1 and 2.

(2) *Small units of low voltage* for street series lighting on 6.6-amp circuits (at 0.6 to 0.7 watt per candle), for stereopticon lamps and automobile headlights. These take currents of 10 amp or less at voltages as low as 4 or 5 volts. The specific power consumption with 1000-hour life ranges from 0.6 to 1.0, or even 1.25 watt per candle, according to the current used.

(3) *Lamps to run on standard lighting circuits (110 volts)*. Large units of this type (of several thousand candle-power) consume 0.5 watt per candle or less.

FIG. 1.—HIGH-EFFICIENCY NITROGEN-FILLED LAMP FOR LOW VOLTAGE CIRCUIT

FIG. 2.—HIGH-EFFICIENCY NITROGEN-FILLED LAMP FOR LOW VOLTAGE CIRCUIT

FIG. 3.—NITROGEN-FILLED LAMP FOR 110-VOLT CIRCUIT

various methods of doing this were tried. The method which has thus far proved most satisfactory is to wind the filament into the form of a tightly coiled helix.

The use of a helically wound filament presents several very interesting features. The life of ordinary single loop filaments is limited by the irregularities in diameter which develop after a considerable amount of tungsten has evaporated. These irregularities, after they first appear, tend to magnify themselves very rapidly, on account of the tendency for the current to overheat any spot which becomes thinner than the rest of the filament. The overheating increases the rate of evaporation and rapidly causes failure.

In the gas-filled lamps, however, when helically wound filaments are employed, a new factor is introduced which entirely counteracts this tendency to overheat in spots. If, during the life of the lamp, any part of the filament should, for any reason, evaporate more rapidly than the rest, so that the filament becomes somewhat thinner, this portion will have less mechanical strength than the rest and will therefore sag more rapidly. The helix will therefore open out wherever the filament becomes thin or becomes overheated. This will cause

Special advantages of the nitrogen-filled lamps are:

1. Much whiter color of the light, due to the fact that the temperature of the filament is 400 to 600 deg. higher than that of ordinary lamps.
2. High intrinsic brilliancy of the filament.
3. Practical constancy of ampere-volt-candle-power characteristics during life.

The figures for specific power consumption given above are watts per horizontal (international) candles measured in the direction perpendicular to the plane of the filament if this is in the form of a single loop. Careful measurements have shown that with helically wound filaments the distribution of light in a horizontal plane is almost perfectly uniform, so that the figures for specific power consumption may be considered to represent also watts per mean horizontal candle.

The ratio of mean spherical to maximum horizontal (practically mean horizontal also) candle-power averages about 84 per cent for the lamps made with single loops of helically wound iron.

An appendix is added on methods of photometry of nitrogen-filled lamps.

Notes on the Standard Apparatus and Method for Measuring the Amount and Character of Atmospheric Pollution.

By John B. C. Kershaw

Observations with the standard apparatus and method of measuring the soot and dust fall of towns and cities (which were fully described in an article by the present writer in the issue of METALLURGICAL AND CHEMICAL ENGINEERING for June, 1913) commenced in October last in the following sixteen towns and cities: London, Hamburg, Birmingham, Glasgow, Liverpool, Manchester, Leeds, Bradford, Crewe, Exeter, Hull, Malvern, Leicester, Newcastle, Plymouth and York. As Hamburg has agreed to adopt the standard form of apparatus and method of collection, it is hoped that other German towns and cities will follow its lead, and that all the European records of atmospheric pollution, wherever obtained, may in time be based upon one uniform method of collection and examination.

The Department of Industrial Research in the University of Pittsburgh has been engaged also for some time past in an investigation of the smoke problem in America, and it would be a fitting close to the labors of the staff engaged in this research, if they could initiate a similar system of observation of the soot- and dust-fall in the more important cities of the U. S. A. The need for the adoption of a uniform system of collecting and examining the character of atmospheric pollution is proved clearly by the fact that all the observations yet made in different towns and countries are worthless for comparative purposes, since each observer has used a different apparatus or method and has applied it under different conditions.

In order that all interested in the subject of atmospheric pollution may be kept acquainted with the work of the London Committee, notes will be published from time to time in this journal, recording the progress made. The regulations which have been issued by the Central Committee for exposure of the gauge and for the chemical examination of the collected water and solid matter are given below. The standard soot- and dust-gauge was fully described and illustrated in the June issue of METALLURGICAL AND CHEMICAL ENGINEERING, and it is only necessary to state here for the benefit of those who did not read the earlier article, that the chief feature of the gauge is an enameled iron funnel with a superficial area of 4 sq. feet.

The gauges are to be placed, if possible, on the ground level, in open spaces free from abnormal dust. The bottles containing the water and deposit are to be removed on the last day of each month, and are to be replaced by thoroughly cleaned empty bottles. Before removing the bottles the gauge vessel is to be washed down with some of the collected water, a brush and rubber squeeze of standard pattern being used to remove any

adherent matter. The chemical analysis of the water and deposit is to be made by a standard method (details of which are given below) and a report of the results obtained is to be sent monthly to the offices of the central committee.

The bottles properly labelled with the name and number of the station, and the period of collection, are to be kept standing in the laboratory for several days, until the insoluble matter has completely settled. The approximate volume of the water in litres should be ascertained at the time of the receipt of the bottles.

The undissolved matter is separated by filtration, the whole volume of collected water being used for this purpose.

The filtration is best effected in the following manner.—

A syphon-tube provided with a glass-tap or pinch-cock on the longer limb, is inserted into the bottle to within about one inch of the bottom. The bottle should stand at a height above the vessel in which the filtrate is to be collected, sufficient for an easy and adjustable discharge of the liquid. The filtering medium which has given the best results, consists of a layer of pulped filter-paper or of asbestos pulp suitably disposed in a Gooch-crucible. The Gooch-crucible should be fitted, by means of an adapter, in the rubber stopper of a graduated bottle of the same capacity as the station bottle. The rubber stopper of the second bottle is also provided with a tube leading to a vacuum pump. The filter is prepared with the pulp in the usual manner, and the filtration takes place under moderate suction. Should the filter become clogged, the pulp, together with any solids collected upon it, may be removed to a porcelain basin and kept for further treatment, while a new filter is made from fresh pulp.

After the clear portion of the liquid has been filtered, the bottom turbid portion may be shaken up and syphoned over into the Gooch-crucible,—the bottle is then washed out with some of the filtrate. Any pulp left over or previously removed, is finally put on top of the solid matter collected in the crucible. Should there be more than one station bottle, it is best to filter first the clear liquid of all, and then the portions containing the solids which have settled.

The Gooch-crucible, after its contents have been washed with distilled water, and dried at 105°C. is weighed; the gain in weight equals the *total insoluble matter*.

The crucible is then placed in an extraction apparatus, and the contents are extracted with carbon bi-sulphide. The loss, after drying, represents the *tarry matters*.

The residue in the crucible is then ignited in a current of air until all the carbonaceous matter is burned away. The residue equals the *ash or mineral constituents* of the insoluble matter of atmosphere.

In order to determine the amount of dissolved matter 250 cc. of the filtrate are evaporated to dryness on a water-bath; the residue is then dried and weighed—this gives the *total dissolved solids*.

The loss on gentle ignition gives the *organic matter soluble in water*; the residue represents the *soluble inorganic matter*.

For the determination of *sulphates* one liter of the filtrate is concentrated, and acidified with hydrochloric acid. The liquid is then boiled, Barium chloride is added, and the precipitated barium sulphate at the end of twelve hours, is filtered off—washed, dried and weighed.

The *chlorides* are estimated by titration of 500 cc. of the filtrate with N/10 silver nitrate solution, taking the usual necessary precautions to ensure the absence of carbon-dioxide (or carbonates) in solution.

The *ammonia* is determined by acidifying 1000 cc. of the filtrate with dilute sulphuric acid, and after concentrating the solution to 100 cc. and making strongly alkaline, distilling the residue into a measured amount of N/10 acid. The excess of acid is then determined by titration with N/10 alkali, and the amount of ammonia present is calculated from the acid which has been neutralized and has thus disappeared.

The *lime* is precipitated as calcium oxalate in 1000 cc. of the filtered water, and is weighed as calcium oxide (CaO).

The *alkalinity* (or *acidity*) of the filtered water is determined

on the usual quantity by means of N/100. hydrochloric acid (or N/100. sodium-hydrate solution) using methyl orange as indicator. The acidity is to be calculated as sulphuric acid,—the alkalinity as ammonia.

Eleven results for each monthly sample of the rain-fall will in this way be determined,—two of these representing the totals of the Insoluble and Dissolved matter, and the remaining nine being the chief constituents of the solid matter brought down with the rain.

As an example of the results obtained with this method of observation, the figures published on page 340 of our issue of

FIG. 1.—DIAGRAM SHOWING THE CONJUNCTIVE SOOT AND DUST FALL OF SCOTCH TOWNS IN TEN WINTER MONTHS OF 1910-1911

June 1913 may be referred to. These showed a total fall of soot-and-dust in the London area ranging from 195 tons per sq. mile per annum at Sutton in Surrey to 650 tons per sq. mile per annum in the center of the City of London.

As a second example, the figures obtained by Chief Inspector Fyfe in Scotland may now be quoted. These are given in Tabular form in Table I. and in diagrammatic form in Fig. 1. The method of collection used by Inspector Fyfe, namely, shallow wooden boxes—one foot square in superficial area and one foot deep, was however less exact than that used for the London observations, and it is quite possible that when the Standard apparatus and method is adopted in Scotland by other towns and cities than Glasgow, somewhat different results will be obtained.

It must be pointed out also that Inspector Fyfe's observations extended only over the two mid-winter months of the years 1910 and 1911, and that owing to the greater amount of coal burned in Winter, and to the greater carelessness of stokers and furnacemen during the long hours of darkness, both the smoke from domestic and industrial chimneys is enormously increased at this period of the year. An average for the whole year calculated on the soot and dust-fall of the two winter months, is therefore misleading and inaccurate.

The continuous records which will be obtained by the standard apparatus and method will, of course, be free from this defect, and it will be of interest to see how the soot-and-dust-fall of Glasgow compares with that of Manchester, Leeds, and other great English centers of manufacturing industry, when the first twelve months period of observations has been completed, and the returns are all in.

In concluding this account of the work that has already been achieved, some extracts may be given from the appeal for funds which has been issued recently by the Committee.

"The co-ordination of observations is the legitimate work of a Committee. The design of new apparatus and methods for carrying out any particular inquiry may properly be left to individual effort, but the selection of a method for the special work of comparison,—the specifications of common conditions,—and

"the co-ordination of the results,—are essentially matters for co-operative action and can only be carried out by a representative body.

"The Committee is now faced with the necessity for finding funds to carry out the work which will devolve upon it, when the scheme of co-operation commences. It is proposed that the several localities shall provide their own apparatus, and also make the analyses of the collected products. But when that has been done, it will still be necessary for the Central Committee to collect and arrange the records and distribute the information acquired to those who are interested in the subject, and this involves a considerable amount of secretarial work with its incidental expenses. Further, a number of questions of detail will certainly arise, with regard to the apparatus used and the methods of analysis, and these can only be answered by means of experimental inquiry.

"The Committee have no claim upon the funds of any existing Society, and that they should personally bear the costs of the inquiry, goes beyond the terms of the Resolution which ap-

TABLE I. AVERAGE AIR POLLUTION IN SEVERAL TOWNS IN SCOTLAND FOR THE WINTER MONTHS OF 1910-1911 (Fyfe)

"pointed them. They therefore appeal to the public for funds "and especially for annual subscriptions in order that the work "now set on foot may be continued, and are confident that the "importance of trustworthy knowledge of the state of the atmosphere as regards impurity justifies them in making this "appeal."

The author's thanks are due to Chief Inspector Fyfe of Glasgow for permission to make use of the diagram and table giving the results of the interesting observations made in Scotland. A full account of these observations will be found in a paper contributed by Chief Inspector Fyfe to the Manchester Smoke Abatement Conference of 1911.

Liverpool, England.

The Murex magnetic concentration process has been applied successfully to both sulphide and carbonate ores. The crushed ore is mixed and agitated with an emulsion of oil and magnetic oxide of iron, after which it is passed under an electromagnet which lifts the particles which have been coated with the emulsion. The process has been used at the Cordoba copper mine in Spain, and the Whim Well copper mine in Australia. At the latter place, carbonate ore is treated, producing a concentrate of 20% to 25% copper from 6% ore, and yielding a recovery of about 80%.

The Growth of the World's Copper Mining Industry in the Years 1898-1912

By John B. C. Kershaw

There is probably no industry that can show such a remarkably rapid rate of expansion during the past quarter of a century as that of copper mining. Taking the average price of the metal produced during this period as £60 per ton, the aggregate annual value of the output of copper by all the mines of the world, has increased from £15,480,000 in 1898, to £60,024,000 in 1912, or by nearly 400 per cent.

In fact, if the aggregate value of the copper produced in 1912, be calculated on the basis of the average price obtained for bar copper in that year (namely £73 per ton) the astonishing total of £73,290,000 is obtained as the present value of the annual output of the copper mining industry. These totals prove that the industry is only second to that of gold-mining, in the value and importance of the metal produced.

The figures used in preparing the tables and diagrams which illustrate this article, are taken from the valuable monthly and yearly statistical circulars prepared by Messrs. H. R. Merton & Co., of London, to whom the writer's thanks are due, for permitting their carefully compiled returns to be used in this way.

AGGREGATE PRODUCTION OF COPPER BY ALL THE COUNTRIES OF THE WORLD IN THE PERIOD 1898-1912

Table I and Fig. 1 give the statistics showing the rapid growth of the world's copper mining industry in the fifteen years ending in 1912.

TABLE I—Total World's Output of Copper—1898-1912

Year	Output in tons	Increase or decrease
1898	429,262	29,896
1899	472,244	42,618
1900	479,514	7,270
1901	516,628	37,114
1902	541,295	24,667
1903	574,775	33,480
1904	644,000	69,225
1905	682,125	38,125
1906	714,100	31,975
1907	713,965	(—,135)
1908	754,180	40,215
1909	839,425	85,245
1910	864,275	24,850
1911	871,920	7,645
1912	1,004,485	132,565

The variations in output from year to year are seen to have been very irregular, ranging from a decrease of 135 tons in

FIG. 1.—THE WORLD'S COPPER PRODUCTION

prices can be accepted as any criterion of the real demand, the relationship between the world's total output of copper and the production of the U. S. A. mines

Table II and Fig. 2 illustrate the relationship between the American copper production and that of the remaining countries of the world, and are useful as showing clearly the pre-dominating position occupied by the U. S. A. mines. The out-

put of these mines in 1912 amounted 554,835 tons, and the percentage of the total output provided from this source, worked out to 55.4 per cent. This figure agrees closely with 55.5 per cent in 1911, and proves that in spite of the large aggregate increase in production during the past year, the advantageous position occupied for so many years by the U. S. A. mines, is still maintained.

TABLE II—RELATIVE PRODUCTION OF COPPER BY THE MINES OF THE UNITED STATES AND THOSE OF OTHER COUNTRIES—1898-1912

Year	U. S. A. Mines		Other Countries	
	Tons	Percentage	Tons	Percentage
1898	234,271	55	195,355	46
1899	262,206	55	210,038	45
1900	263,502	55	216,012	45
1901	265,250	51	251,378	49
1902	292,870	54	248,425	46
1903	307,570	53	268,203	47
1904	365,050	56	278,950	44
1905	389,120	57	293,005	43
1906	409,650	57	304,450	43
1907	392,520	55	321,445	45
1908	423,300	56	330,880	44
1909	490,280	57	349,145	43
1910	484,935	56	370,750	44
1911	485,865	55	385,064	45
1912	554,835	55	449,650	45

This advantage is clearly indicated in Fig. 2, and it can be seen that the margin between the aggregate output of the U. S. A. mines and that of all other countries, is widening instead of diminishing. This paramount position of the U. S. A. mines in the copper mining industry undoubtedly enables the American financiers to exercise a control over the supplies of the metal and to regulate prices, but this is outside the scope of this article to discuss.

THE COPPER OUTPUT OF THE TWELVE MORE IMPORTANT COUNTRIES IN THE PERIOD 1898-1912

Tables III and IV and diagrams III and IV give the production figures from Messrs. H. R. Merton's returns, for the twelve more important countries (excluding U. S. A.) for the fifteen years ending 1912. Although these twelve countries have greatly increased their aggregate output of the metal during the period under review, their proportion of the total output has remained stationary, at slightly under 45 per cent.

These twelve leading countries rank in the following order of importance as copper-producing countries, when judged by their output of the metal in 1912: Mexico, Japan, Spain and

1909	56,325	47,000	52,185	34,400	35,785	24,105
1910	61,515	46,755	50,255	40,315	35,235	25,715
1911	60,905	55,000	50,930	41,840	29,595	24,930
1912	70,845	65,500	58,930	47,200	37,305	34,710

Portugal, Australasia, Chili, Canada, Russia, Peru, Germany, Africa, Norway, Servia. The figures for many of these countries exhibit the striking progress of the copper mining industry during the period under review Japan, Mexico, Russia, Australasia, Canada, and Peru showing extraordinary developments of this industry.

Mexico which in 1898 produced only 16,435 tons of the red metal, produced 70,845 tons in 1912, and has permanently displaced the Spanish Peninsula, from its place of importance as

a copper-producing country. The Mexican mines are controlled chiefly by American financial interests, and the output varies considerably according to the state of the copper market. In recent years a large number of old mines have been reopened and worked again, but these are closed down when the price of copper falls below a remunerative level.

Japan has shown steady progress as a copper-producing country during the past fifteen years, and has increased its output from 25,175 tons in 1898 to 65,500 tons in 1912, thus ranking third in the list of producing countries.

Australasia and Canada.—The copper mining and smelting industries in these two countries have also shown notable expansion in the period covered by the table—the Australasian output having increased from 18,000 tons in 1898 to 47,020 tons in 1912, and the Canadian figures showing an increase from 8104 tons to 34,710 tons.

Russia is another country in which the copper mining industry has experienced great developments in recent years, the figures in Table IV showing an advance in production from 6260 tons in 1898, to 33,010 tons in 1912.

Peru, however, is the country which can show the most remarkable expansion of the industry during the past fifteen years, the increase in this case being from 3040 tons in 1898, to 27,165 tons in 1912. The output has, however, remained stationary since 1910, and the inference is, that the copper mines of Peru have about reached the upper limit of their productive capacity. Otherwise the great rise in the price of copper that occurred during the years 1911-1912, should certainly have brought about an increased output in the latter year.

Chili, which so long ago as 1897 produced nearly 50,000 tons of copper, is once again increasing her production, and has advanced from 24,850 tons to 37,305 tons in the period covered by Table III.

Africa has advanced her output from 7110 tons in 1898, to 16,370 tons in 1912, and when the ores from the much talked-of Katanga mines, north of the Zambesi river, are being smelted on a large scale, a notable addition to the copper exports of this part of the world may be expected. At present the smelters erected in the Zambesi district are not working satisfactorily, the restricted fuel supply having created greater difficulties than was anticipated.

Serbia is a new addition to the ranks of the producing countries, and although the Serbian mines only commenced to pro-

FIG. 3.—MAJOR COPPER PRODUCING COUNTRIES OTHER THAN THE U. S. A.

pansion similar to those given above. The aim of those governing the production of the copper mines situated in these countries, is well known to be that of maintaining a steady output, rather than to force production and exhaust the ore reserves, during the successive short periods of high prices.

Figs. 3 and 4 show clearly the rapid expansion of the copper mining industry in ten out of the twelve countries, during the period 1898-1912, and summarize in graphic form, the information as to progress given above.

VARIATIONS IN VALUE FOR THE PERIOD 1898 TO 1912, AND THE RELATIONSHIP BETWEEN OUTPUT AND PRICE

The figures showing the average price of standard bar copper are given in Table V., which also contains the figures for the world's total output of copper in each of the years named. Fig. 5 gives these figures in graphic form, and it will be noticed that the "curve" for the price variations, shows three periods of high

prices with three depressions. The price boom of 1898 to 1899 was due to the formation of the Amalgamated Copper Com-

pany in the States, the second and third booms have been due to more natural causes, namely the extremely active state of trade in the shipbuilding and electrical engineering and allied industries, at a period when there was some slackening off in the rate of production in the copper mining industry, and in consequence some depletion of stocks.

As pointed out by a writer in the London Times recently, activity in the shipbuilding industry creates a great demand for copper, and "if the man-in-the 'street or the speculator in 'copper-warrants were to 'make an exhaustive examination of a first-class high-speed ocean liner, he would be 'amazed at the quantity of copper, plain or as brass required 'about her engines, her auxiliary plant, her sanitary arrange-

1912	10,010	17,165	23,920	16,370	10,980	7,240

duce copper in 1908, their output in 1912 amounted to 7,240 tons. The Balkan war will, however have stopped all development here for the present year.

The old established copper mining industries in Spain and Portugal and in Germany do not show any figures for its ex-

"ments, her kitchens, her saloons, staterooms, and staircases, "even her portholes, rails and scuppers."

The estimated consumption of copper in 1912 was 1,024,000 tons. The stocks were reduced by 20,000 tons between January and December 31, in that year, and the output amounted, as already stated, to the huge total of 1,004,000 tons. How long the mines of the world can continue to supply copper at this rate is a question, the answer to which only the future can disclose. There will undoubtedly come a time, however, when the supplies of ore of the red metal will become exhausted, and when copper will appreciate in value owing to this cause. It will then be the duty of the chemist and metallurgist to provide a satisfactory substitute for the metal which has so long occupied a foremost place in the metal industry of the world, and it will no doubt be found that *aluminium* or some of the *aluminium alloys*, can be used for many of the hundred and one purposes, for which *copper* is now universally employed.

Liverpool, England.

Applications of the Microscope to Industrial Work

The season's first meeting of the New York section of the American Electrochemical Society was held on October 17 at the Chemists' Building and was very enjoyable and successful. The attendance was large, the big lecture hall being almost completely filled. Although the meeting lasted well beyond 11 o'clock, the attention of the audience never lacked.

Great credit is due to the chairman of the section, Mr. **Lawrence Addicks**, superintendent of the U. S. Metal Refining Company, of Chrome, New Jersey, for having arranged an exceedingly interesting program. The subject of the evening was the application of the microscope to industrial work. All the papers were profusely illustrated with most instructive and in part brilliant lantern slides. As it is a physical impossibility to reproduce here the many microphotographs shown, it is rather difficult to do justice to the meeting in this report.

The Metallography of Carbon

The first paper was presented by Professor **G. A. Roush**, of Lehigh University. In an investigation of the internal construction of carbon products and of the kinds of raw materials suitable in their manufacture, success was obtained by the application of the ordinary principles of preparing samples of metals for metallographic examination. The ordinary metallographic methods proved satisfactory also for carbon products, with the exception that some special means of etching were required to bring out the structure of the sample, since the acids used for this purpose with metal samples do not attack carbon. Relief polishing, used as with metals, proves satisfactory in some cases; this is secured by polishing the sample on a soft, yielding surface, such as broadcloth, so that the soft parts of the sample are worn away, leaving the harder parts in relief.

For ordinary work, etching with heat gave good results. A sample, after being polished, was heated to a low red heat until the oxygen of the air had attacked the polished surface just enough to dull it a little, and then the sample was cooled in a blast of air. This oxidized the softer parts of the sample faster than it did the harder parts, and thus developed the structure. Samples of carbon treated, in this way showed the individual grains of which the body of the material was composed, the thin films of binder holding these grains together,

and the pores between the grains. A sample can then be judged in regard to its porosity, and in regard to the size and shape of the grains from which it is made up. The size and shape of the grains will be found to vary widely with the method of crushing, and the porosity varies with the grain size and the pressure under which the material has been formed into shape.

By carrying matters a step further, and examining samples of the various raw materials used it was found that the more important of these showed a characteristic structure, so that the individual grains of sample from an unknown source could be identified. When this was found to be possible, the methods of measurement of microscopic particles used in petrography were made use of, and in this way, approximate quantitative analyses of materials could be made. A known sample, containing 33 per cent of petroleum coke by volume, showed by analysis 32 per cent.

Carbon electrodes which had been converted into Acheson graphite showed the outlines of the individual grains of the raw material, and frequently showed the characteristic structure of the raw material. Whether this retention of the original structure was due to incomplete conversion into graphite, or whether it was analogous to a pseudomorphous crystal, was not determined.

The examination of fine powders under the microscope sometimes can be greatly facilitated by moistening with a very dilute solution of gum arabic, pressing together firmly, smoothing off a surface with a spatula, drying, and then examining the grains making up this smooth surface.

Professor Roush's paper was illustrated by numerous lantern slides showing photomicrographs of characteristic structures.

Micrometry as Applied to Alloys

A paper on this subject was then presented by Dr. **C. H. Mathewson**, assistant professor of metallurgy at Sheffield Scientific School, Yale University.

In a general sense, methods in which the microscope is used are termed micrographic methods; when applied in a rigidly quantitative sense they are termed micrometric methods. The discussion in the first part of the paper is based on the Al-Zn system, as recently revised by Rosenhain and Archbutt.

The conditions represented in an earlier diagram of Shepherd were very simple. According to it no intermediate phases are formed, but both aluminium and zinc crystallize as solid solutions, aluminium dissolving some 45 per cent of zinc and zinc dissolving several per cent of aluminium at the eutectic temperature. The eutectic mixture contains 5 per cent of aluminium.

Rosenhain and Archbutt's later diagram, based on very accurate and delicate measurements, is of considerable complexity. This is mainly associated with the presence of an inter-metallic compound Al_2Zn_3 which escaped the attention of earlier observers as it is formed in most of the alloys by reaction between a primary crystalline phase, rich in aluminium and residual solution containing about 85 per cent Zn, with little evolution of heat.

In this investigation the errors due to incomplete reactions became evident. Thus the primary crystals may be enveloped by a layer of compound as it first forms, and the cores of the crystals are thus protected from further change. Rosenhain and Archbutt emphasize the caution which must be used

LAWRENCE ADDICKS, CHAIRMAN NEW YORK SECTION
AMERICAN ELECTROCHEMICAL SOCIETY

in applying the method of thermal analysis, owing to the possibility of incomplete adjustment of equilibrium during the brief period of time in which all observations are made. This possibility must be considered in all cases where it is desired to interpret micrographic evidence quantitatively, since any change in solubility, any chemical reaction or other variety of transformation involving crystalline phases, is likely to proceed incompletely, particularly if it occurs at a fairly low temperature.

By annealing their alloys at a temperature slightly below the peritectic horizontal, Rothenhain and Archbutt were able to prevent envelopment and conduct the reaction quantitatively.

In addition to the qualitative interpretation of photomicrographs, as authors commonly apply theme in a semi-quantitative sense. In the present case, having established the fact that the reaction may be rendered complete by annealing at a suitable temperature, it is obviously in order to seek the concentration at which both reacting phases are completely exhausted in forming the compound by examining a series of micrographs. When this result is attained there will be no residual eutectic to be seen in the alloy. Rosenhain and Archbutt show a photomicrograph in which a much smaller quantity of the white constituent is to be seen. This alloy contains 80 per cent zinc and is evidently very close to the composition of the pure compound. In a third photomicrograph, corresponding to 77 per cent zinc, no eutectic is to be seen. We cannot conclude that this is the exact composition of the compound, since it forms solid solutions with an excess of Al, but, it is clear that the pure compound lies between 77 and 80 per cent zinc, and, according to the thermo-analytical results, the eutectic disappears at 78.8 per cent. The formula Al_2Zn_3 requires 78.35 per cent. The different results are quite sufficiently in accord. There appears to be no reason why we may not make use of these photo-micrographs in a rigidly quantitative sense. The structure-elements appearing in them are zinc, containing about 1 per cent Al, according to the authors, and Al_2Zn_3 , both, probably of invariable composition under the present thermal treatment. It is true however that the composition of the zinc-rich phase should be more thoroughly investigated for these purposes. When this point is settled and when we have ascertained the relative densities of the two constituents, we are in a position to calculate the actual percentages of each constituent by weight from area measurements on the photo-micrograph.

Assuming that the equilibrium diagram is available in correct form, we are thus able to calculate the percentage of Al or Zn present in any alloy within this part of the diagram by properly annealing the alloy, preparing a representative section, examining it under the microscope, and photographing a typical portion of the surface, or tracing it directly from the screen to save time. It is, of course, highly important to sample the metal carefully in the first place, as in ordinary analysis. This may be done in the usual way, by taking drillings or chips from different parts of the specimen if the may be melted down easily without change in composition. It is better to take a few coarse pieces from different parts of the specimen and melt them down under a flux. With low melting metals, this may be done as rapidly as the ordinary process of sampling and solution. In this method of analysis, a second important process of sampling or selection occurs under the microscope. At this point, the whole surface should be examined carefully and a thoroughly representative spot chosen for the graphical treatment.

While, in most investigations, the formulas of intermetallic compounds and other fundamental concentration values have been located by thermal analysis, it is quite as feasible to use the micrometric results in a similar manner, i. e., instead of represented eutectic periods of constant temperature as ordinates at the various concentration points and extrapolating concentrations at which a zero or maximum period occurs, we may represent the percentage area of eutectic in the different concentrations as ordinates and extrapolate in the same manner. This possesses an advantage over the thermo-analytical

method in that it is not necessary to use the same volume or weight of metal in the different determinations (cf. Tamman, *Z. anorg. Chem.*, 45, 292, 1905).

Dr. Mathewson has used Rosenhain and Archbutt's photomicrographs in this way with the following results: The area of the white constituent in the 80 per cent Zn alloy, determined with the polar planimeter, is 25.6 per cent of the whole; in the 77 per cent Zn alloy, it is 8.3 per cent. Assuming a linear decrease in the volume percentage of the white constituent, with the concentration (expressed in terms of Zn and Al_2Zn_3), the zero value obtains at 78.1 per cent Zn. That this result agrees almost exactly with the true composition of the compound Al_2Zn_3 , 78.35 per cent zinc, must be regarded as fortuitous, since the photo-micrographs were not selected by the authors with a view to micrographic work and, the planimetric measurements were not made on specially large scale drawings.

In using the planimeter on the 77 per cent Zn alloy the isolated white areas were joined to one another in the manner suggested by Sauveur (¹). The tracing pin was then moved over portions of the area boundaries in one direction and returned over the remaining boundaries following the connecting lines in the reverse direction, so as to nullify their original effect on the reading.

In practically all metallographic papers, we find semi-quantitative deductions based upon some of the photomicrographs. But Dr. Mathewson points out that it is dangerous to rely upon general appearances instead of actual measurements of area, even though approximate. In this case, a calculation based upon the equilibrium diagram shows that the eutectic should contain 19.4 per cent of the compound by weight. When treated so as to reach equilibrium below 236 deg., there is a possibility that the areas corresponding originally to compound will be still less, owing to decomposition of the compound and its replacement by the Zn-rich phase and another Al-rich phase, some of the former probably coalescing with the original light constituent. We do not know the densities of the two constituents, and cannot calculate the area which should correspond to the above percentage by weight, but it is certainly true that not more than one-third of the whole area is occupied by the dark constituent in photomicrograph. Rosenhain and Archbutt's photomicrographs of the slowly cooled eutectic. This conclusion was reached by tracing the outlines of the dark constituent upon finely ruled co-ordinate paper, estimating the number of squares included within these outlines, and calculating the total number as a percentage of the whole. As a result of two separate measurements, 28.6 and 29.2 per cent of the area is found to represent the compound.

It is clear that the relation between the squares and the individual areas to be estimated may be chosen so that a relatively large number of squares are entirely included within an individual area, leaving a comparatively small portion of the area open to errors of measurement. In many cases, this method of measurement will be found more convenient and probably more accurate than the planimetric method. By comparison, such methods are cutting out the separate images and weighing the paper, or measuring the portions of a straight line intercepted by the different constituents, are laborious or inferior in point of accuracy. This method may be applied very rapidly by tracing the outlines of the constituent in question upon a thin sheet of co-ordinate paper upon which the image is focused through a clear glass plate at the back of the camera. The author has made some determinations of iron in spelter in this manner at the Hammond Laboratory of the Sheffield Scientific School.

Previous investigation has shown that iron crystallizes from zinc in the form of beautifully developed individuals containing from 7 to 11 atoms of zinc per atom of iron. This represents a case very favorable to the development of a micrometric method of analysis, since some 13 times the weight of

¹Trans. Am. Inst. Min. Eng., 26, 880 (1896).

the added element, iron, is clearly visible as a distinct structure element. This case was discussed in some detail by Dr. Mathewson.

Probably more attention has been devoted to the determination of various elements entering into eutectic relations with copper than to any other micrometric problem. Heyn (*Zeit. L. anorg. Chem.*, vol. 39, p. 1, 1904) first demonstrated the structural relations brought about by the solidification of copper containing oxide and introduced a method of determining the oxygen content by area measurements. It is now recognized that this method is sufficiently reliable to be of practical value and far more convenient than any chemical method, although area measurements of eutectic structures in the presence of a primary constituent are likely to give variable results, and the exact quantitative effect of impurities, such as As, Sb, etc., has not been determined. According to this method, the relative areas of eutectic and primary copper crystals are determined by measurement, planimetric or otherwise, on the micrograph. The eutectic is composed of 3.45 per cent cuprous oxide and 96.55 per cent copper, according to Heyn. Since one unit of oxygen by weight corresponds to 8.95 units of cuprous oxide, which in turn correspond to 28.99 units of eutectic, the oxygen is represented in the micrograph by a distinct structure element 261.46 times its own weight. We may make errors of several per cent in estimating the weight of the eutectic by area measurements without seriously affecting the results as expressed in oxygen.

Hofman, Green, and Yerxa have determined the oxide in samples of refined copper by using the planimeter on enlarged micrographs (magnified 1150 diameters) and by analysis, according to Hampe's method. Bardwell has described the use of a similar method at the Great Falls smelter and gives comparisons with ordinary analytical data which clearly indicate the value of the method in technical practice. Dr. Mathewson has used the micrometric method of determining oxide in cast copper with students in the Department of Mining and Metallurgy at the Sheffield Scientific School for several years.

Huntington and Desch have tested the micrometric method of analysis very fully in the case of copper-phosphorus alloys which also contain the non-metallic element in the eutectic condition. In this case, the eutectic is composed of copper crystals containing 0.175 per cent phosphorus in solid solution and copper phosphide, Cu_3P , the total composition of the mixture being 8.27 P + 91.73 per cent Cu. The amount of phosphorus held in solid solution by the copper appears to be constant in the cast and annealed alloys. A very different factor, however, renders the ordinary planimetric determination of the phosphorus content by measuring the eutectic areas very inaccurate. This lies in the variable composition of the metal surrounding the primary copper crystals. Normally this should be of definite (eutectic) composition, but during the cooling of the alloy subsequent to eutectic crystallization, or during the annealing, the small copper crystals of the eutectic have coalesced with the large primary crystals in the immediate vicinity and the phosphide has also coalesced around the enlarged copper crystals. It is evident that the eutectic no longer contains 91.73 per cent Cu if we measure it from the boundaries of the black crystals, but somewhat less than this. Huntington and Desch were able to correct the measured areas of the black crystals with surprising accuracy by measuring the area of the enveloping belt of phosphide and deducting the amount of eutectic copper normally corresponding to this phosphide from the black crystals. When the phosphorus content is low the net work of eutectic is originally fine and, as a result, all of the copper coalesces with the large crystals leaving a pure phosphide network.

In the micrometric treatment of eutectic structures great care must be taken to recognize and allow for coalescence. In some cases, it is practically absent as in copper-phosphorus alloys containing copper phosphide as a primary constituent, i. e., those high in phosphorus. There also appears to be relatively little interference of this sort in the copper-copper oxide alloys previously discussed.

In forecasting the future possibilities of micrometric methods, Dr. Mathewson pointed out that we must be mindful of the fact that the microscope offers primarily a means of studying the proximate composition of metallic material and that the direct results obtained in this manner can be translated into ordinary analytical results only in favorable cases and under closely regulated conditions. It is, therefore, more logical to expect future development to lie principally in the direction of interpreting and applying the proximate results themselves in the estimation and specifications of quality, without regard to chemical compositions, except within prescribed limits. It is conceivable that, in many cases, it may be far more important for the manufacturer to know that his product conforms to a certain standard in respect to size of crystals, percentage of area occupied by inherent crystalline phases, or micrographic character in general, than to possess elaborate analytical detail concerning the ultimate composition.

It appears more desirable to record the micrometric results directly in terms of the structure elements measured, and seek to make full application of them in this form rather than to attempt the calculation of ultimate composition from them. For example, the character of the copper-cuprous oxide eutectic is influenced by the presence of arsenic. In the absence of precise information on this point, it does not appear desirable to calculate the oxygen in an arsenical copper under the assumption that the eutectic contains 3.45 per cent Cu_2O . It seems better to record the percentage area of primary copper crystals along with qualitative data regarding the appearance and distribution of the eutectic.

Obviously, it is impossible to draw any deduction concerning the ultimate composition of an alloy composed of a homogeneous solid solution from micrometric results. It is a matter of common practice, however, to control the heat treatment of such alloys by measuring the size of the crystals or counting the number present in a given area under given magnification.

Dr. Mathewson concluded that we have in micrometric analysis a valuable aid in the scientific or technical examination of alloys, which is often superior to ordinary analysis as regards the character and extent of the information returned, but which ordinarily constitutes a source of distinctive results rather than a substitute for ordinary analysis. A satisfying total of analytical information is obtained by judiciously combining the two methods.

Microstructure of Raw and Manufactured Copper

A really remarkable series of microphotographs was shown and discussed in a paper of Mr. W. H. Bassett, Technical Superintendent and Metallurgist of the American Brass Company of Waterbury, Conn.

The microphotographs shown indicated the changes in structure due to working copper, that is, they showed the differences between copper in the cast and wrought condition.

The pictures also showed clearly the influence of the oxygen which is always present in copper, upon its structure, both in the cast and wrought condition. The presence of the copper-copper suboxide eutectic is readily distinguished microscopically, and several quantitative methods have been devised for determining the amount of oxygen in the copper by the aid of the microscope.

Certain impurities in the copper, such as antimony, modify the character of the eutectic, and their presence can be readily distinguished through a microscopic examination.

A photograph was shown indicating the presence of a considerable quantity of the copper-copper suboxide eutectic in over-poled copper where such copper contained a comparatively large percentage of sulphur. The picture exhibited was that of an over-poled specimen carrying 0.012 per cent sulphur.

A number of pictures were exhibited showing the relation between the set and microstructure of wire bar copper. Also, the influence of the amount of oxygen present upon the soundness of the bars.

Photomicrographs of native copper samples from Lake Superior were shown. These have the same type of structure as wrought copper. The crystals, however, are very much enlarged probably due to the very slow formation. The pressure exerted upon this copper in the rock produces the same form of slip bands as those shown in the crystals of cold rolled copper. A number of photomicrographs were shown indicating the various types of structures of hot rolled, cold rolled, drawn, and annealed specimens. Attention was called to the oxygen spots in this material and their absence in wrought specimens of copper which had been deoxidized at the time of casting. Several diagrams indicating the influence of cold working upon the physical and electrical properties of copper were discussed, and the influence of annealing at various temperatures on these properties, and, also, upon the microstructure noted.

The hope may be expressed here that Mr. Basset's able paper will be published in full with the full series of microphotographs.

The Microscope in Mineralogical Analysis

A paper on this subject was presented by Mr. Gilbert Rigg, research engineer of the New Jersey Zinc Company.

Mr. Rigg has probably been the first to apply color photography to metallography. He exhibited a striking series of Lumiere plates showing photomicrographs of zinc ores, with resolution of the minerals present. This beautiful set of colored photomicrographs fittingly closed the official program.

In view of the late hour, no time was left for extended discussion. But Professor William Campbell also showed some interesting slides of photomicrographs.

Microscope Exhibit.

A very interesting exhibit of microscopes of the firm of Ernst Leitz, New York, was inspected by many of those present and explained by Mr. A. Traeger after the close of the meeting. As this exhibit showed the remarkable advances made in recent years in the design of microscopes especially for metallographic work, some brief notes on the principal types exhibited should be interesting.

The Leitz micro-metallograph is constructed after the le Chatelier principle and embodies some suggestions of Prof. Guertler, of the Technische Hochschule in Charlottenburg, and Dr. Wm. Campbell, of Columbia University. It is being used by the leading metal industries in their laboratories distributed over various departments. The special advantage of the Leitz micrometallograph is its extremely easy manipulation, the image, once observed by the eye, can be immediately transferred to the ground glass or plate respectively, after the ocular tube has been removed out of the optical axis. The instrument itself is mounted on a heavy triangular optical bench, thus eliminating any vibration which is most essential, considering the fact that practically in every industrial laboratory, vibration to a certain extent is experienced, this due to the factory being at a close range of same.

This instrument was shown with three different optical outfits. First, the achromatic, or ordinary microscope objectives, are used mostly for routine investigations and especially in cases where the instrument is not desired for the photo-micrographic study of metals, opaque ores or alloys.

Second, the semi-apochromatic objective series is advanced in its constructions over the achromatic objectives, this due to the increase of flatness of field, color correction and resolving power. This series of lenses is recommended, in preference to the achromats, for the visual observation and photo-micrographic study.

Third, the apochromatic objectives, however, represent a series of lenses of highest efficiency. The color correction, resolving power and flatness of field, have been increased to the highest state that optical science provides for at present. The apochromats come especially recommended for the photo-micrography of metals, alloys and opaque ores, and the results with these lenses are superior to those which may be obtained with either one of the optical equipments mentioned above.

Another interesting instrument exhibited was a small metallurgical microscope (Leitz Model B), constructed after the suggestions of Prof. Wm. Campbell. This metallurgical microscope is of a smaller type and recommended for use in those laboratories where the metallographic study is only attended to when occasion arises. This instrument, combined with a small upright photo-micrographic camera, serves advantageously for the photo-micrographic study of metals, alloys and opaque ores. A decided advantage of this apparatus is its detachable model. While small metal pieces are placed on the stage of the microscope (the latter is supplied with rack and pinion movement for cross focus) this method of investigation would not be possible for large metal pieces. In this instance, the upper part with microscope tube is removed, the microscope table, mounted on column, eliminated and the upper part attached direct to the horseshoe base. The microscope stand, if assembled in this way, can be placed direct on large metal surfaces.

The Leitz-Greenough binocular microscope, which was also shown, is supplied with a prism arrangement, allowing the use of both eyes for the stereoscopic vision of cross minerals, metal pieces, etc. The stereoscopic image is erected, this contrary to the results obtained with the regular compound microscope.

Another interesting exhibit was the Leitz petrographic microscope, constructed after the suggestions of Prof. Chas. Berkey, of Columbia University, especially for work in laboratories of industrial concerns and educational institutions. The optical equipment which is used in connection with this instrument covers an essential outfit needed for the routine observation of minerals, etc.

The exhibit also included a special microscope stand for the advanced study of mineralogy, and another microscope stand specially designed for chemical laboratories where frequently the observation of specimens under polarized light and then again the regular biological observation is necessary. The polarizing adjuncts, therefore, are mounted in such a way that they are easily removed in order to render the microscope available for biological observation.

The next meeting of the New York section of the American Electrochemical Society will be held jointly with the New York section of the American Institute of Mining Engineers on Thursday, November 20, at the Engineering Societies Building, 29 West Thirty-ninth Street, New York City. The subject will be the Metallurgy of Zinc, and figures will be presented by Messrs. G. C. Stone, W. R. Ingalls, and Victor Engelhardt.

Calculating Sulphuric Acid in Vats.—The following tables, given by W. Shellshear in the *Mining and Engineering Review*, Australia, facilitate the calculation of the quantity of acid in a vat. The vat is first measured and its water content obtained and tabulated per inch of depth. From this the amount of acid in the vat is read as tons of water. This reading can be converted into tons of mono-acid by multiplying by the sp. gr. of the acid, and by the percentage strength of acid corresponding to this sp. gr. That is: Tons of mono-acid = tons of water X (sp. gr. of acid $\times$ per cent strength of acid), or tons of mono-acid = tons of water X. The value of X can be calculated for different specific gravities.

Thus, if the sp. gr. of acid is taken by the t waddell hydrometer at 15° C., the table would be:

Tw.	X	Tw.	X	Tw.	X	Tw.	X	Tw.	X
80	763	92	819	104	876	116	1,054	128	1,181
81	712	93	820	105	946	117	1,064	129	1,191
82	722	94	839	106	956	118	1,075	130	1,201
83	731	95	848	107	967	119	1,085	131	1,212
84	741	96	858	108	977	120	1,096	132	1,224
85	751	97	869	109	987	121	1,107	133	1,233
86	761	98	879	110	996	122	1,118	134	1,244
87	770	99	889	111	1,006	123	1,125	135	1,256
88	780	100	895	112	1,015	124	1,139	136	1,267
89	791	101	905	113	1,025	125	1,150	137	1,278
90	800	102	916	114	1,035	126	1,160	138	1,289
91	810	103	926	115	1,044	127	1,170	139	1,301

Example: A vat holds 18 in. sulphuric acid of 105° Tw. The vat when full to the same depth of water holds 5 tons. Then the mono-acid in the vat = 5 X, or 5 $\times$.946 = 4.73 tons.

The Brush Discharge

By A. Vosmaer, Ph.D.

The literature on the brush discharge is very scarce. Most scientists work on too small a scale, while practical men have neither the time nor the opportunity to study the brush discharge as such.

For this reason I hope that the following account of my personal experience of fifteen years with brush discharge phenomena will be found useful.

Part I.—The Brush Discharge through Air without the Use of Solid Dielectrics

There is perhaps no essential difference between the passage of electricity in a solid, a liquid or a gas, although it is customary to call the first conduction, the second electrolytic (ionic) conduction and the third convection. It would perhaps be better to consider all of them to be convective in character.

In any case a potential difference between the two points considered is essential for a current; if there is no P. D. there will be no current. It is immaterial whether we think of P. D. as the first cause or whether we look upon resistance as the essential for a P. D. again.

In the whole of physics the rule holds that there can be no force exerted unless there is a resistance against which said force can be applied. Sometimes action creates its own reaction (static back pressure). There is a general tendency in nature to reduce all "free energy" to a minimum, thereby increasing the entropy to a maximum; all water at a high level will run downward; all differences in temperature will be equalized at the cost of the higher temperature; never will any amount of heat as measured by heat units be capable of raising the temperature of something that has a higher temperature. In one word, in nature's free state all energy change is in the direction toward decrease of intensity and increase of capacity.

Now if said change is not checked in some way or another it will exhibit itself; the usual way of checking is by means of the unknown entity called resistance.

Ohm's famous law is usually expressed by saying that the current is the quotient of tension and resistance, but it would be more logical to say that tension is the product of current into resistance. The first way, however, is much more convenient when reasoning in a popular way upon some common thing.

A potential difference, however small, even when infinitesimal, will always cause a current of electricity to flow through a solid conductor (if we may use the term of flow). But this is not true for an electrolytic conductor, in which case the impressed e.m.f. has to be greater than the counter e.m.f. of polarization in order to produce a current.

In gases the problem is still much more complicated as we shall learn.

We may neglect the counter e.m.f., but there is a lower limit of e.m.f. below which no current will pass through a gas. The value of this lower limit of e.m.f. varies with such factors as the temperature, the degree of ionization, the shape and state of electrodes, etc. Therefore, the value of this lower limit is not a constant at all and cannot be given even approximately. It may be in the neighborhood of a hundred volts, or much higher.

The discharge of electricity in a gaseous medium depends on quite a number of factors, such as the pressure of the gas, its temperature, its nature. Further, it depends on the shape, on the size and spacing of the electrodes, and on the finish of each of them. Moreover, there are some secondary influences such as radiation (ultraviolet light) and the effects of a magnetic field or an electric field. It also depends on the kind of current supply, its tension, frequency, wave form and the circuit as a whole.

We shall discuss these influences in succession. Evidently the problem is rather a complicated one so that we shall leave out of consideration many important details.

PRESSURE

In the first place we shall have to confine ourselves to the study of the discharge in a space filled with gas and will not consider the phenomena in vacua, as these would form a treatise many times the length of this one.

It may be mentioned that a pressure lower than the atmospheric, greatly facilitates the passage of a current down to a certain point where there is so little gas left that there are not enough ions to convey the electricity.

The brush discharge is affected in such a way that even a small diminution of pressure changes its character altogether. In view of this fact, one may feel inclined to try higher pressures. But the same holds true there, though in a less degree. We have tried up to three atmospheres, but every increase in pressure seemed to make it more difficult for the brush to keep up its being.

Watson, when constructing his high-tension voltmeter, has taken advantage of the fact that at high pressures gases become insulators. They are very poor conductors when liquefied; the conductivity of liquefied gases is of the same order as that of pure water.

TEMPERATURE

I have had no occasion to experiment either with very high or with very low temperatures, but it is probable that the first will be detrimental to a true brush discharge and the second will not have much effect until extreme temperatures are reached.

MOISTURE

It is several years ago that Steinmetz, experimenting on high-tension sparks, published the result that moisture has little effect on the dielectric strength of air, and what influence it has points to increase rather than decrease as one would suspect at first thought. The brush discharge does not seem to be sensitive to moisture; although there is some evidence pointing in the direction of decrease of P. D. for the same brush, I would not dare to claim this as a fact.

KIND OF GAS

Since the object of my researches has been the manufacture of ozone, I have always been experimenting with air or oxygen and have not tried other gases except hydrogen and carbonic acid. No marked change in the character of the brush could be detected when going but superficially into this matter. It would have been very interesting to know just what happens when other gases are subjected to the very strong influence of the brush discharge, but the scope of my work was already too big so that I could not go too far beyond it.

IONIZATION

It is a very strange fact that though the brush discharge is powerful it does not seem to have much force of ionization. When a discharge of as much as two watts was confined in a small tube of glass and the air blown to a charged electroscope, after having been filtered through cottonwool, it did not change the position of the gold leaves, no matter whether they were negatively or positively charged.

This result surprised and annoyed me because I had expected to be able to prove that the brush discharge is essentially a positive one. I have every evidence that it is a discharge from the positive wave and not from the negative, but there are many investigators who hold the reverse to be true.

KINDS OF DISCHARGES

Before proceeding I wish to call particular attention to the fact that for the present moment we are considering discharges in free air, no solid dielectric being between the electrodes; the latter case will be considered afterward.

In free air, then, at atmospheric pressure and normal temperature, there are four distinctly different kinds of discharges, viz., the glow, the brush, the spark and the arc.

The glow is the first stage. It is merely a bright spot on the electrode and causes no appreciable loss of energy unless very prominent, in which case it is very liable to become a brush

¹The corona loss, which is caused by the glow discharge, is but small compared to what it would be were it a brush discharge.

The interest in the glow discharge has greatly increased since in high-tension power transmissions the voltage has been varied so much as to bring about the corona effect.

There is much information now to be had on this subject of the corona effect which a few years back had no interest for the practical men. The corona loss starts at the point

FIG. 1.—BRUSH DISCHARGE

when the glow is about changing to the brush. There is no sharp line of demarkation between the glow and the brush discharges, though in their most characteristic forms they show no resemblance to each other.

The true *brush* (a photograph of which is reproduced in Fig. 1) has very distinct features. Its color is a dark bluish

FIG. 2.—BRUSH DISCHARGE

violet, its hissing sound and "wind" are well known,² its shape is a straight stem detached from the electrode from which it starts or rather separated from it by a dark space, and at its end there is a widely spread out cone. This cone or conical

FIG. 3.—SPARK

end may be flattened into a fan-shaped end, but not in all directions.

It is very important to remember this special form of the brush, as it gives a clue to many phenomena which are apt to appear when one is building up an ozone apparatus.

The ignorance of this particular behavior of the brush ac-

²The names, Silent Discharge and Dark Discharge should be dropped.

counts for many a failure in actual practice of ozonators, as we shall presently see.

The brush is a three-dimensional discharge; at the best it may be reduced apparently to two dimensions, that is, it may be flattened in one direction so that it looks as though it had no thickness. Still one should never lose sight of the fact that it has to have some extension in space in all directions.

For practical purposes this means that one cannot possibly have a continuous line of discharge. There must be free

FIG. 3A.—SERIES OF TEN CONSECUTIVE SPARKS

space left between the different discharges, or in other words, it is necessary not to use a perfect smooth line, like a razor blade, but a dented one, for the discharger.

Fig. 2 explains this sufficiently. The latter has been exaggerated purposely. In actual praxis, using 1.3 millions of points for a 20-kilowatt apparatus, there were 36 points used per inch. Sharper and longer points allow to use 50 points per inch.

All this refers only to spacing in one direction. We shall see later on what the spacing has to be in the other direction, that one being more evident on account of the visible spread out at the base.

The brush discharge passes over again into the *spark* without a sharp boundary between them, although here again the brush and the spark, in their most characteristic forms, do not have any resemblance.

The spark is characterized by its white yellow color, its peculiar zig-zag path, which under certain circumstances can

FIG. 4.—SPARK MIXED WITH BRUSH DISCHARGE

be made straight, its loud report and its oscillatory motion, in contrast to the brush which is unidirectional and not intermittent.

Fig. 3 shows a photograph of a spark of 10 in. in length given off by a powerful 12-plate Whinshurst machine. Fig. 4 shows the mixing of a spark and some faint brush discharge from the same machine, run without its condensers. Fig. 3a represents a series of ten consecutive sparks.

If circumstances are such as to allow of it, a spark will

change to an arc. This is most dangerous of all forms of discharges on account of the tremendous amount of energy transformed into heat and concentrated in a small space; it generally means ruin of the apparatus unless checked in due time or taken care of and controlled by some method such as those now used in the systems of making nitrous compounds out of the air.

We shall not discuss in detail all these discharges, but had to mention them because we shall have to refer to them.

FIG. 5.—ARC

The arc (Fig. 5) is very hard to photograph because it is so restlessly moving about. Its characteristic features are its faint blue color, its intense heat and its continuity.

POLARITY

When we speak of the brush we always mean the positive brush because there is no real negative brush, although there is a negative discharge under the same circumstances.

In Fig. 5a we show side to side the positive and the negative discharge. The difference in appearance is striking, but could have been shown even much more strikingly had I taken other prints.

If matters are arranged in such a way that the pointed discharger is made the negative pole, all we obtain instead of the beautiful brush is a tiny little violet spot about one-tenth the size of the positive brush or sometimes even less than that. The demonstration of this very marked difference is quite easily made. It used to strike most scientists who watched it. A powerful Rhumkorff induction coil is the best source of supply for this experiment, as it gives practically unidirectional high-tension current, the intermissions are too short to be noticed, and if the output is taken up by a good number of points, say several thousand, then there is no interference from undesired sparking.

FIG. 5A.—POSITIVE BRUSH (LEFT) AND NEGATIVE DISCHARGE (RIGHT)

It is known that a Rhumkorff gives a secondary current of very peculiar wave form, but that is no objection.

ELECTRODES

Shape and Size of Electrodes.—There are many variations to be tried. First let us take two flat surfaces, the discharge invariably will take place at the edge because here the situation differs from that at other points, the electric charge being greatest at the edge. In the center of said flat surfaces there can be no discharge whatever, while from the edges an irregu-

lar and rather poorly developed brush may occasionally start.

The next experiment is to take two spheres. There can be no brush discharge under ordinary circumstances of operation. If the spheres are of equal size, the equipotential surfaces have the form of spherical shells or rather ellipsoidal shells, quite unfit for our purpose.

Two parallel wires are unsuitable for the purpose of the brush discharge for the same reason, namely, the fact that the equipotential surfaces are coaxial with the wires.

Two crossing wires may give rise to a brush, but will not do so unless very carefully arranged. As a rule a wire is a very bad shape for a brush and this is fortunate, since this is the reason why after all the corona loss does not amount to very much even on very high tension.

Two points cannot give off a brush discharge, unless under very special circumstances; it is very difficult to obtain a brush and it is impossible to work with it. All these facts are easily told, yet, until we understand the exact conditions of the true brush, they seem puzzling.

If we refer to Fig. 1 it is easily understood that the arrangements of electrodes just summed up cannot give a brush discharge. Since the origin and end of the discharge are different, the two electrodes should also be made different; that is,

we must not take two electrodes of equal but of different shape.

Let us now consider these cases and also take into consideration another circumstance, viz., that of sign or polarity.

A great many combinations could be considered, but as none of them except one will answer our purpose we can be very brief about the others. It is of no use summing up all of the combinations; just a few may be enough to bring out the evidence clearly.

FIG. 6.—BRUSH DISCHARGE AND POTENTIAL GRADIENT

A positive plate and a negative sphere give no brush.

A positive plate and a negative wire give no brush.

A positive plate and a negative point give no brush.

A negative plate and a positive sphere give a brush.

A negative plate and a positive wire give a brush.

A negative plate and a positive point give a beautiful brush.

(The reader will permit us for the sake of brevity not to dwell upon the fact that, of course, such terms as sphere and point require a more precise definition, but as the boundaries of discharges are just as vague as those of shapes, which after all differ only in degree of curvature, there is no need of further definitions and we trust on the reader's good will for understanding.)

So much on the question of shape. Evidently there is no choice left. The best arrangement is to have the discharge from a pointed toward a flat surface, and if we make a drawing of the potential gradient that is likely to occur it will be clearly like the curve shown in Fig. 6.

It might be said here that the photograph of the true brush in Fig. 1 has been taken from one in free air from a small sphere against free air, no opposite pole being provided so as not to influence beforehand the free development of the brush.

In actual work one uses alternating current because direct current of very high tension (say 10,000 volts) is not so easily available as is alternating current. As it is only in the half-period in which the point is positive that it discharges a

brush, the negative half-period is lost, not with respect to energy, but with respect to time.

There is a simple way to make up for this, shown in Fig. 7. Here each discharger proper is intended to emit the electric discharge from its sharp edged side when positive and to receive it on its flat back when negative (if we may express ourselves in a popular way). There evidently is no gain at

FIG. 7.—ARRANGEMENT OF DISCHARGE

all except in the reduction of the size of apparatus for a given capacity.

The sharper the point the better it is; that means the less voltage it takes to have a discharge. In actual practice I used at first steel needles made especially to suit the purpose. But when I had to increase the capacity of the apparatus from two to twenty kilowatts it could not be done in that way on account of the high cost, as there were 100,000 needles per kilowatt. For this size of ozonator I used No. 35 pure nickel strips toothed like a saw (36 teeth per inch) and for the other electrode a nickel strip of suitable width, the width depending on the polar distance. In my case the width was $\frac{3}{4}$ in., the polar distance being $\frac{1}{2}$ in.

The size of the dischargers proper is of much greater influence than one might imagine at first thought. The flat surface should be $\frac{1}{4}$ more than the polar distance.

The size of the positive sharp electrode matters little, but

FIG. 8.—SPACING OF DISCHARGES

it should not be extremely short as it should be free from the influence of the electric field caused by its back.

There is a very convenient check to find out whether or not an ozonator has been designed properly. If it is properly designed the energy it takes is directly proportional to the total length of dischargers (or number of points).

This statement will seem self-evident. However, those who have been working in this field know that at the beginning

when the experimenter does not yet know all these details he is every now and then surprised and very often puzzled as to the reason why after an apparatus has been built for say 100 watts, on making it twice as large it does not take twice as much energy.

That will happen when the rules governing the brush discharge are overlooked, due to ignorance. I may say here that it has taken me over 12 years of experimental work and practice to bring the whole affair to a satisfactory end.

We will now describe an instance in which multiplication of discharging points does not correspond to an equal multiplication of wattage.

Spacing of Electrodes.—The spacing apart of the different parallel dischargers proper is an interesting point of great importance. It bears on the principle of electrical shadow.

An example will make clear what I mean.

In Fig. 8 *a, b, c, d, e* are the dischargers proper, mounted in such a way as to allow of easy displacement sideways when under test.

One strip (*a*) will give a perfect series of brush discharges when connected up to the source of electricity, a 10,000-volt transformer.

Now move a second strip near to its side. At a distance from the first strip of say anything above an inch it will work just as good as the first. The energy will be twice what it was before (case *c*).

But when the second strip is moved nearer and nearer to the first one, the discharge is losing in brightness (*b*). Now let us move it away again till all is as bright as possible (*c*). Suppose this occurs at a distance of $\frac{1}{4}$ in.

Put in a third strip, make the distance again $\frac{1}{4}$ in. Then the second discharger will be extinguished and only Nos. 1 and 3 will work (case *d*).

Repeat this with a fourth discharger and so on and it will be seen that any but those at the end are extinguished. The inside dischargers will not discharge at all.

The energy consumed is therefore not proportional to the number of strips, unless these are spaced apart so far that they do not longer interfere with each other's action (case *e*), that is until they are beyond each other's shadow.

Since this spacing depends on the polar distance, at greater polar distance the brush spreads out wider and requires more spacing.

This experiment, which is very fascinating to watch, explains why multiplication of dischargers not necessarily means equivalent increase in capacity. It also makes clear the reason why from a flat surface one does not obtain any discharge from the central part, but only from the edges.

I may once more draw attention to the fact that we are speaking of discharges in free air without any solid dielectric being placed between the electrodes. If this is done, as we shall see later on, the conditions of working are altogether altered.

(3) *Material and Finish of Electrodes.*—It is quite immaterial of what material the electrodes are made. I tried nearly all the more easily available metals and never found the slightest difference.

For the purpose of ozone making platinum would be the best, or gold, but, of course, these are out of question on account of excessive cost. Silver is rapidly corroded by ozone, and so are aluminium, brass, zinc, iron, but copper stands well and so does nickel.

But besides resistance to corrosion there is another property to be considered, viz., that of hardness. It is a very curious phenomenon that the perpetual bombardment of the negative electrode should result in an actual wear. After a year's use the flat nickel strip shows flaws, it has the appearance of a skidded rail (in miniature). But one would not expect wear on such a hard metal as nickel by bombardment of air molecules.

There is no wear whatever on the positive strip so evidently the wear is not through metallic particles of the positive strip. This is important to note for a wear of the positive electrode

would indicate a change in the condition of working. Fortunately this does not happen.

The discharging positive electrode should be sharp-pointed, not sharp-edged. A razor blade gives very poor brushes. There must be real points because the brush must have a support for its stem. Perhaps it is better to say that the stem of the brush must have an inducement to build itself up, this inducement being provided by discontinuities in the line made either like teeth of a saw or as true points (needles).

The finish of the negative electrode should be smooth, without protruding parts or sharp edges or corners. These ought to be rounded off.

ELECTRIC AND MAGNETIC FIELD

The influence of an electric field is very much disturbing and in large apparatus it may be very difficult to avoid it.

We have already spoken of the disturbance caused by the own electric shadow of the discharges, but here we have in view the stray fields caused by the metallic parts of the apparatus.

We have experienced great trouble from this cause and the most convenient way to avoid it was to have part of the apparatus built of wood instead of metal. These stray fields are uncontrollable and cannot be neutralized by proper grounding. By the way, it may be mentioned here that grounding a high-tension circuit is not such an easy thing as it looks.

A magnetic field affects the brush discharge just as it would affect an ordinary alternating current. A strong field tends to "blow it out" and a tendency of sparking is set up.

As to the influence of electric radiation, such as ultraviolet light, this question has not yet been settled. Some people claim a very decided influence of ultraviolet light radiation on the working of brush discharges. I have never been able to detect any at all, but this may have been due to the powerful discharges which I used.

CURRENT SUPPLY

(1) *Source of Current Supply.*—For the study of the discharge, a statical machine is a very convenient source for the current but that is all. Any practical use is out of question for well known reasons.

The use of Ruhmkorff induction apparatus is the next step for an experimenter. The wattage that can be obtained is much higher than that from the former machine, but it is still of no practical use. Full credit may be given to the very interesting experiments one is able to make with it, but it can only be employed for research, not for actual use.

A high-tension direct-current machine, or direct-current on the Thury system has for a long time been my desideratum, but so far I have not been in a position to experiment with this kind of current.

Alternating current has been my regular source of supply, the generator giving 110 volts, the transformer up to 60,000 volts for experimental work. Under practical working circumstances I have used 10,000 volts. (I may call attention here to the fact that at the time when I started my experiments, viz., in the year 1898, such high tensions were an absolute exception in my country, Holland, and the only possibility of using 60,000 volts was to build the transformer myself.)

(2) *Tension of Current Supply.*—It goes without saying that there is an intimate connection between the width of the air gap and the tension of the current. It is easy to understand that the general formula will be $I' = a + bl$ which means that in general the potential difference required to send the discharge through the air gap will be made up of a constant factor a and one depending on the width l of the gap.

One may thus adapt either the polar distance of the dischargers according to the tension of the current, or one may regulate the voltage according to the given distance.

When it comes to ozone making, however, and highest efficiency is sought after, there is no longer any such liberty in choice.

Down to a certain limit, the best yield per kilowatt-hour, as well as the highest concentration (two quantities that are in opposition to each other), are obtained with the smallest pos-

sible air gap, called polar distance. This point has to be considered very carefully.

For the true brush discharge there is a lower permissible limit of polar distance. Under the most favorable conditions this lower limit is about $\frac{1}{4}$ in. for safe working, however, it is hardly possible to go below $\frac{3}{8}$ in., and as a rule we have worked our machines at $\frac{1}{2}$ in.

This settles the question of tension, which may be about 10,000 volts (a.c.). Of course, it should be as high as possible in order to get the highest current density and thereby maximum of wattage, the limit being set by the production of sparks between the dischargers instead of the regular brush

FIG. 9.—EFFECT OF WAVE FORM

(3) *Frequency of Current.*—The danger of sparking can be very materially diminished by raising the frequency of the current to an extra high value. We have tried frequencies up to 600 periods per second instead of the usual 50 (100 in my country in 1898).

The advantage of the possibility of using a higher frequency is counteracted by the fact that the output per kilowatt-hour is thereby reduced. When taking resource to high-frequency Tesla currents, there is hardly a possibility of the occurrence of sparks, but we have the drawback of an enormous decrease in output.

These facts indicate advantages in the use of direct current for ozone making purposes. Perhaps somebody will take this up in future.

(4) *Wave Form.*—The wave form of the electromotive force is of theoretical, rather than practical importance.

Still when we consider the question of wave form, it becomes clear why we can have a brush discharge without dielectrics.

Referring to Fig. 9, let the line $a-b$ represent the minimum voltage at which a discharge will occur. Then, if the top c represents the voltage at which sparking will take place, it is quite clear that if we know of a way to keep the actual voltage between the dischargers below that point c , say at the line $c-d$, there will be no sparking, since the voltage is not high enough for the spark discharge, the polar distance being given

FIG. 10.—CONNECTIONS

That is what is actually being done when we arrange a discharge to take place from sharp-pointed electrodes.

A spark discharge presupposes a certain amount of electrical charge. For just this reason it is not continuous but an intermittent, oscillatory discharge. The brush, however, is a steady flow and for this reason it does not give the electric charge an opportunity to accumulate for a spark; from a sharp point the electricity flows off so easily that there is no chance for a spark.

From this inference it should follow that a peaked curve would give more security against sparking than a flat one. In actual practice the deviation from the true sine wave is not so large as to make any difference for the brush discharge.

(5) *Safety Devices in the Current Supply*.—The discharge from either one point against a flat surface, or from a series of points of any desired length against a flat strip, all of suitable and harmonic design, can be a true brush discharge and will remain so for any length of time, *unless* there comes some disturbance, either caused by a raise of tension, or by a particle of dust or oxide that may cause a spark to be formed.

Now a spark means a lowering of resistance, of course, at once followed by an increase in current density at that spot. This means raise of temperature, causing again a decrease of resistance, etc. Evidently when a spark is once started it will not only remain but will increase.

When we deal with an ozone apparatus of many hundred thousands of points, it would not be possible to avoid all and every disturbance that might happen to come. But as it is of great advantage to have the apparatus work without any attendance at all, some safety device has to be applied and this is what we will now briefly discuss.

Fig. 10 shows a special way of making the connections (patented by me in 1902); in the circuit from the secondary terminals of transformer *T* there is a self-induction *L* in series and a capacity *C* in shunt with the wires that lead to the ozonator *O* which represents a certain resistance.

Through the combined effect of self-induction and capacity the secondary tension will be raised (Ferranti effect) to such an extent that, while the ratio of transformation of the transformer is 70, so that under ordinary circumstances the secondary tension would be 7700, yet in this case it rises to 10,000, but not so unless there is a *certain* resistance at *O*.

Suppose this resistance drops off, say, on account of a spark, then the rise just mentioned from 7700 to 10,000 volts will not take place. The voltage will be less. As soon as this is the case, the cause for the spark has also ceased or the possibility for its maintenance has vanished, the result being that any spark just about to start or already started, will, by its own being, make its continuity impossible. It checks its own existence and it does this in a most beautiful and startling way with surprising accuracy.

The raise of tension is the greater the more the product *LC* approaches unity. It can never be greater than under this condition.

From a theoretical standpoint it is immaterial whether we obtain the raise of voltage through increase of *L*, or increase of *C*, but when the load is heavy, *i.e.*, the resistance is small, then one should rather increase *C* as an increase of *L* causes too much phase lag.

From the foregoing it will be understood that in the design of a large-sized ozonator every item has to be carefully calculated and the whole system has to be in perfect harmony. If this is so there is no trouble, no attendance is required. When the apparatus has once been adjusted to the point of best working the occasional sparks are taken care of by themselves (some little sparking does not interfere with the proper working and is hardly to be avoided on account of particles of rust on the electrodes).

The principal advantage lies in the fact that with this arrangement the arc discharge is an *absolute impossibility* (even when the tension is raised 20 per cent purposely, to demonstrate this fact).

It should be borne in mind that in this arrangement there is no spark gap, as in the Tesla method, which would cause high-frequency discharge.

Perfect and most strikingly beautiful brush discharges can be obtained in this way, and in an absolutely reliable working condition.

As explained, this way of making the connections has to be considered as a safety device. The discharge itself is not altered at all. It may be just as good when the usual conditions are employed. This brings us to the second part.

Part II.—The Brush Discharge with the Use of a Solid Dielectric

As a result of the desire of having some safeguard against the dangerous arc discharge, several devices have been invented and applied. Since the days of the first laboratory ozonator the principle of placing a solid dielectric between the electrodes has been applied by numberless "patentees." We shall deal with this at greater length and, therefore, will first mention other systems.

The drawback of the use of glass is its liability to crack and that is why many have endeavored to do without it.

It was in 1894 that Schneller announced that he was able to obtain the brush discharge without making use of any solid dielectric. This was at first considered to be an impossibility, but Schneller proved the soundness of his assertion by constructing a 2-kw apparatus which did the work, to everybody's surprise.

Schneller inserted a "high resistance" in the high-tension circuit, said resistance to be of the order of 20,000,000 ohms and made of a glass tube filled with 80 per glycerine. The principle, though interpreted in an altogether wrong way, had the merit of being quite new and Schneller's experiments were pioneer work.

For his 2-kw apparatus he used seventy-five of these glycerine-filled tubes of 20,000,000 ohms each, in parallel with his 50,000-volt circuit. The discharge he obtained was a beautiful sight but viewed from the commercial standpoint the system proved to be a failure because of its extremely low efficiency.

From the scientific standpoint it is interesting to point out that said "resistance tubes" do not work as ohmic resistance, but as a pseudo capacity. It has taken me quite some time to find that out, but it is beyond question.

It is easy to demonstrate that an ohmic resistance does not do the work but, on the contrary, provokes arcing instead of preventing it. This fact is quite in accordance to the theory of the discharge.

A few years later Schneller took out a patent for the use of enamel as dielectric, but had the shrewdness not to call it such. He said it was used for having a more equal and smooth surface of electrode!

The next thing that came out was the use of high frequency for the purpose of ozone making. Now it happens to be so that the unsurpassed beauty of the Tesla dark discharges has no bearing on their efficiency and that killed the system.

It is true that with this system there is no danger at all from arcing but as after all the object is ozone manufacture rather than display of beauty the system has never entered the market.

Another device was that of Otto, who tried the use of revolving electrodes in order to either prevent arcing or when arcs were formed to extinguish them by drawing them out.

The system never did any good because arcing should not be *corrected* but *prevented*. Arcing causes nitrous compounds to be formed and causes great damage to the apparatus.

After having been experimenting with all known systems and after studying them carefully, I came to the conclusion that in order to obtain the brush discharge and nothing but this particular one, it is not necessary either to use solid dielectrics between electrodes, or a high resistance in series, or a high-frequency current, or revolving electrodes. All that is really necessary is a thorough knowledge of the subject and according to that, we should endeavor to realize in actual practice what theory indicates as advisable.

This has led me to my system and the fact that I admit frankly that my system has not any more *raison d'être* on account of its low efficiency will make it clear to the reader that it is not as a rival or competitor that I now classify all systems as dead ones, except one which is based on the use of a solid dielectric.

The reason why I have been dwelling so long on those others is just to point out the *importance* of the latter one and to prove that its survival is not a mere chance or commercial attainment but the logical outcome of merit.

In order to fully appreciate the glass-dielectric ozone ap-

paratus, it was necessary to learn by experience that it is the best we have at present and probably for the near future.

When using a solid dielectric there is no chance for a spark nor for an arc to set up. The discharge is always right, whatever the arrangement, and there is but one difficulty left, viz., that of failure of the glass.

Many failures on this account are due to overloading. Too much energy on a given surface causes too much heating up and this will always result in a breakdown, sooner or later, but usually sooner.

The perpetual heavy dielectric strain on the glass also causes occasionally or perhaps always, a change in the nature of the glass, which as is well known is very far from being a body in molecular equilibrium. Dielectric hysteresis is another source of heat and danger.

The success of a glass ozonator, evidently, depends therefore, for the greater part on the quality of the glass. This is a physical and a chemical problem rather than a technical one for the present.

The technical side of the glass ozonator is no problem at all for those who are familiar with the business. The failure of so many "systems" is the logical result of ignorance.

The second great advantage of glass-dielectric ozonators is that they allow of a very small polar distance of dischargers, and that means high concentration as well as high output if the current density is great, the difference in yield being up to ten times as much. This puts all the other systems out of service.

Thus it happened that after twelve years of elaborate experimental and practical research, I finally had to give up my system for a better one, the original glass dielectric system. But facts are facts and science takes no notice of personal pride and ambitions.

One advantage I have gained and that is impartiality, since now I have not a system of my own to bring to the front and to recommend and am at liberty to consider the matter from the impersonal scientific standpoint.

There are numberless patents for ozonators. It would fill up a book were we to consider or even mention them. Most of them are valueless, some of them are ingenious.

Some people prefer glass plates to glass cylinders, others do the reverse. Some believe in the beneficial effect of cooling the air, others do not. Some people think much of complicated arrangements, others believe more in simplicity.

There are, however, some details of interest, but as we intend to discuss ozonators on another occasion, we shall not refer to these here. If the dielectric system has so many advantages and but one disadvantage, namely the treacherous character of glass, why not use any of the many other solid dielectrics? That is a question likely to be put forward. It is because no other dielectric will do.

Ozone being such a powerful oxidizing agent, is detrimental to most dielectrics of organic base. Rubber, for instance, is destroyed in a few seconds. So none of that group can be used.

Moreover, the material in question has to possess certain mechanical properties and has to have a certain thickness. For this reason shellac or other varnishes cannot be used as they cannot be had in sufficient thickness.

The whole group of those conglomerates lack homogeneity and for that reason cannot be used. Others, again, like fibre, asbestos, paper, etc., are too porous for electricity, which "eats" its way through.

Then come some minerals. Most of them are not to be had in convenient shape. Slate is also porous. Mica will answer the purpose but poorly, as it cannot bear very well the heating up; its lamellation is a further disadvantage, the layers becoming more and more separated from one another until finally it is not one thickness but several. Micanite is no better.

Bakelite did not yet exist at the time when I tried every one of the dielectrics, so I do not know its behavior.

Of the fused materials there are enamel, porcelain, and vit-

rified silica. The first can never be applied ruthlessly to a surface, and even if it could it would be no good, its dielectric strength being too low and its thickness too small.

Porcelain fails through lack of homogeneity. So does, for the present, the vitrified silica; it is very fragile and its fusion has not been quite so complete as to remove all flaws, air bubbles, etc. It may be, however, that it will play an important rôle in ozonators in future because its quality is rapidly improving every year.

So it is that only glass combines all the requirements of dielectric strength, mechanical strength, chemical strength and variety of shape and thickness.

One more point of scientific interest is the fact that the dielectric strength of ozone is much higher than that of air. If one leaves the ozone in the apparatus so as to get an increasing concentration the tension of the current has to be raised continuously in order to keep the wattage constant. This circumstance puts a limit to the maximum concentration of ozone obtainable; it may be in the neighborhood of 30 grams per cubic meter.

A fact, generally overlooked, is that a large load of ozonators brings a considerable amount of capacity into the circuit which should be checked by self-inductance.

The Metallurgy of Sudbury Copper-Nickel Ores

One of the two important commercial deposits of nickel-bearing ores in Canada is in the locality of Sudbury, Ontario; the other is in the Cobalt district in the same province. The treatment of the Sudbury ores is covered in some detail in a 200-page *Monograph* recently issued by the Department of Mines, Ottawa, Canada. The work is by Dr. A. P. Coleman, and is entitled *The Nickel Industry*.

The Sudbury ores include essentially only four ingredients: a magnetic sulphide of iron, which is practically free from nickel and copper; a sulphide of nickel and iron, which is non-magnetic; a sulphide containing equal parts of iron and copper, which is non-magnetic; and a variable amount of rock matter which may be of several different kinds, in the main non-magnetic, norite or the products of its weathering predominating.

Some of the ores are low in copper and high in iron, and an attempt has been made to convert these directly into ferro-nickel, but the experiment was a failure on account of the presence of too much copper. Magnetic concentration naturally suggests itself as a method of treating an ore which contains a magnetic mineral and several non-magnetic or feebly magnetic minerals, and a great deal of work has been done along this line, but without success. The reason for the failure is disclosed by an examination of photomicrographs, which show that the pentlandite ($2\text{FeS}, \text{NiS}$) and chalcopyrite ($\text{Cu}_2\text{S}, \text{FeS}$) ramify through the pyrrhotite (magnetic pyrite) in a very intricate manner.

At most of the mines a certain amount of hand-picking is done, in order to reject ore of too low-grade to be profitably treated, but no efforts have been made at concentrating this low-grade material. The mechanical separation of the sulphides from the rock can never be complete because of the intimate mixture of the two in the pyrrhotite-norite, into which the solidier ore usually passes. In any event it is unlikely that much concentration will be attempted until the supply of high-grade ore becomes less abundant.

Metallurgical Processes

The usual metallurgy of the Sudbury ores includes four distinct processes. (1) roasting to remove part of the sulphur; (2) smelting in blast furnaces to produce standard matte; (3) resmelting the standard matte in converters to make a matte of 75 or 80 per cent nickel and copper; and (4) the separation and refining of the nickel and copper. The first three processes are carried on in the Sudbury district, and the methods employed do not differ essentially at the different plants. The refining operation is carried on in other countries (United

States, Wales and Norway) and is accomplished by a different process at each place. More or less secrecy surrounds the refining processes.

Heap-roasting is usually adopted for reducing the sulphur content of the ore to a point where it is suitable for smelting to standard matte. In preparation for a roast-heap, a layer of cordwood or dead pine is laid down to a depth of a foot or 18 in., the space between the larger sticks being filled with smaller pieces to make a rather level surface. Small channels filled with kindling wood lead at intervals of 8 or 10 ft. toward the center of the pile, so as to light the whole heap uniformly. Coarse ore is dumped on this bed, making up about two-thirds of the whole. This is followed by medium sized ore, and the pile is then covered with fine ore. The whole pile will contain from 2000 to 3000 tons, arranged in rectangular form, with flat top and sloping sides.

The wood is fired and burns for about 60 hours, after which the sulphur in the ore continues to burn without further aid. From three to four months time is required to roast such a heap, and at the end of that time the sulphur content has been reduced to about 10 per cent and the iron is more or less completely oxidized. In the earlier stages of the roast a good deal of sulphur is sublimed from the interior of the heap and condenses in the upper part, but eventually this is burned away. Some leaching occurs when rains come on, and the colored water running from the heaps gives evidence of the loss of soluble metal. The roasted ore is usually well sintered, and may require the application of explosives to break up the larger masses.

Smelting at Copper Cliff

The metallurgical practice of the Canadian Copper Company, at Copper Cliff is described in the monograph by Mr. D. H. Browne as follows: When properly roasted the ore contains about 10 or 11 per cent sulphur, and is removed from the roast heaps by steam shovel and taken in 50-ton drop-bottom cars to the ore bins. The ore trains which supply the blast-furnaces consist of eight or nine side-dumping cars. The first three carry the coke charge, amounting to from 10 to 12 per cent of the weight of the charge; the next three carry the ore charge, which usually amounts to 9000 or 10,000 lb. of roasted ore; another car carries 2000 or 3000 lb. of Crean Hill ore, which does not require roasting as it contains only 12 to 14 per cent sulphur. Sometimes, if the ore is well roasted, 2000 to 3000 lb. of Creighton green ore can be added to the charge. Furnace scrap and quartz, when used, are carried in separate cars. The quantity of the latter varies from nothing to 2000 lb. per charge, according to the silica in the ore.

If the furnaces are choked by silicious ore or fine ore, lime may be used for a few charges instead of quartz. The coke is dumped in the furnace first, then the ore with its flux, then the scrap or floor screenings. The blast is normally 24,000 cu. ft. free air per furnace at about 25 to 35 oz. pressure. If the furnaces develop blow-holes due to choking from fine ore, the heat is thrown to the top of the furnace and crusts are formed. These may be cleaned out by charges of green ore and lime, which melt easily and carry the heat to the lower part of the furnace, undercutting the crusts, after which they can be easily removed by barring. There is no regular rule for running the blast furnaces, as the charge varies from day to day, and even hour to hour, with changes in the chemical or physical quality of the ore.

The five blast-furnaces smelt from 40,000 to 45,000 tons of ore per month, the amount of green ore varying with the condition of the roasted ore.

Green ore alone could be used in the blast-furnaces, but would produce a low-grade matte and throw an undue amount of work on the converter department, as shown by the following interesting comparison: To make 100 tons of Bessemer matte per day from a 10 per cent furnace matte would require fourteen basic-lined converters; from 15 per cent matte would require seven basic converters; from 20 per cent matte, five converters; from 25 per cent matte, four converters; and from 30 per cent matte, three converters.

Adoption of Basic-Lined Converters

Prior to March, 1911, the Canadian Copper Company had in operation ten stands of acid converters, with shells 84 in. by 126 in. lined with the usual quartz and clay mixture. Each shell consumed 3000 cu. ft. free air per minute at 9 to 11 lb. pressure. On a 36 per cent furnace matte, one lining lasted about eight hours and produced seven tons of finished bessemer matte, 80 per cent copper-nickel. With a 30 per cent furnace matte, one lining produced only 5.3 tons of bessemer matte.

As the amount of metal lost in furnace slag depends very much on the grade of furnace matte made, this pointed to the desirability of making lower grades of furnace matte, with cleaner slags, throwing on the converters every year an increasing burden. The lower grade furnace mattes contained not only less copper-nickel, but also more iron; in a 40 per cent furnace matte, 1 lb. of copper-nickel is accompanied by 0.88 lb. iron; in a 30 per cent matte by 1.28 lb.; and in a 20 per cent matte by 2.4 lb. It is evident that lower grade mattes will require longer to blow than high grades, since the iron must be oxidized and the air capacity of the converters is fixed. One hour and five minutes is required to blow a 36 per cent furnace matte to produce a ton of 80 per cent bessemer matte, while one hour and fifty-five minutes is required for the same operation with a 30 per cent furnace matte. Further, since the amount of matte thrown out of the converter by the blast is about the same per hour, the capacity of the converters on low grade matte is reduced by reason of the greater amount of matte blown out during the longer period of blowing.

Basic-lined converters have been adopted in place of those just referred to, and considerable advantage has accrued from the change. The basic units are larger, and can handle larger quantities of matte. Owing to the manner of construction, there is practically no material slopped from the converter during the blow, and hence less furnace matte is required to produce a ton of bessemer matte. The slag is made lower in silica, which means economy in flux, and the converter slag contains less copper-nickel than in acid converting.

These basic converters are 37 ft. 2 in. long by 10 ft. diameter, outside measurement, running on four tread rings 12 ft. diameter. The opening for escape of gases during the blow is in the center of the cylinder, and there are no tuyeres directly under this opening. There are forty-four tuyeres, 1¼ in. diameter and 7 in. apart. The length inside the lining is 33 ft. 3 in.; the bottom is 2 ft. thick; the back or tyure wall is 18 in. and the front wall 15 in. thick. The roof is a 12-in. arch, and the brick directly around the tuyeres is 24 in. thick. There are two openings in the front wall opposite to, but above, the tyure line. Slag and matte are poured from these openings.

The basic converter takes an initial charge of about 60 tons of furnace matte. About 10 per cent of quartz rock, previously dried, is dumped into the converter and the blast turned on. Blowing is done entirely by the clock; the first slag is skimmed in from one-half to three-quarters of an hour, and while the slag is being poured off, 5 or 6 tons of furnace matte is poured into the converter. After the slag is poured, about 3 tons of quartz is added and the charge blown for another fixed time. The length of the blow, the amount of slag removed, the weight of matte added after each skim, and the per cent of flux required are all factors of the grade of matte and have to be determined by experience. The blowing and addition of matte is continued until the converter contains from 70 to 80 tons of finished product, after which the matte is cast into molds. This may require from 300 to 400 tons of furnace matte, and from 30 to 50 hours blowing time, depending on the matte grade.

Reverberatory Smelting

In order to provide a suitable method of treating an accumulation of flue-dust and fine ore, reverberatory furnaces were built in 1911. Briquetting and sintering had been tried on these materials, but without success, either on account of failure of the method or extravagant cost. The reverberatories

are interesting as being the first designed to burn pulverized coal. Pulverized-coal firing had been tried at Cananea, Mexico, and at the Highland Boy smelter in Utah, but the furnaces were not specially designed for this purpose.

The reverberatories at Copper Cliff are 112 ft. x 19 ft. hearth area. The extreme height inside is 6 ft.; the bottom is an inverted arch of magnesite brick with a spring of 12 in. The foundations were made by building a trestle about 14 ft. high, and pouring slag from this to build up within walls a solid block of slag 10 ft. high above the yard level. On this foundation the furnace walls were built, and slag was poured inside these to form a furnace bottom 2 ft. thick. Tunnels were formed in the slag foundation at either side of the furnace at the yard level, and through these two tunnels the melted converter slag is brought to the furnaces and matte taken back.

The hearth as formed by leveling up the poured slag with concrete, to provide an inverted arch of the same curve as the magnesite lining. On this one layer of fire-brick was laid flat, $2\frac{1}{2}$ in. thick; over this 2 in. of ground chrome ore was laid, and on this the final bottom of 9 in. of magnesite brick, laid in a mixture of ground magnesite and linsed oil. Expansion strips of wood were laid between every six courses, allowing an expansion of $\frac{1}{4}$ in. to the foot. The tap hole is placed to retain about 12 in. of matte in the hearth, so that the bottom is always protected by a pool of matte.

Slag is removed at either side of the furnace, about 11 ft. from the front. The space at the front usually occupied by the slag door, slopes up gradually from the hearth to form a straight outlet for the products of combustion, which pass through dust-chamber flues to the stack.

The most interesting feature of the reverberatory practice is the method of firing. Coal is pulverized to about 200-mesh and delivered to bins at the end of the furnace. From these bins it is taken by five variable-speed screw conveyors 4 in. diameter, which deliver the coal to five burners, dropping it in front of the nozzles which carry air from a fan. The air blast sends the coal into the furnace in the form of a spray of dust which burns like fuel oil. Each burner can be run independently, and the amount of coal or air varied at will.

The *Monograph* from which the foregoing excerpt has been taken, contains also copies of the patents of the Mond, Hybinette, and Orford refining processes, which also have been noted in earlier issues of this journal.

Solvay Foundations

In connection with the fiftieth anniversary of the commercial birthday of the Solvay process, Ernest Solvay has made a number of splendid foundations. Our Berlin contemporary *Chemie*, probably the only daily chemical paper in the world, writes in its issue of September 26, as follows:

In the year 1861 Ernest Solvay, then 22 years old, an employee of a gas plant near Brussels, Belgium, applied for a patent for making soda from brine with the aid of ammonia and carbon dioxide. People thought then, however, that soda made by this process would be more expensive than Leblanc soda and no financier was willing to invest the money for starting a factory.

Only after many efforts, sufficient capital was raised to start a small experimental factory near Brussels. It soon appeared that the new process was essentially superior to the Leblanc process and in 1863 the first factory was built by Solvay at an expense of 136,000 francs (\$27,200).

Today, after 50 years, the Solvay soda factories of Belgium and other countries have 35,000 employees and workmen.

In connection with the 50th anniversary of the starting of the first factory, Solvay has made the following foundations and donations.

Donations were made to every official and employee as follows: Every official received a check to the amount of one monthly salary for every four years of service with the company, every workman received ten francs and an extra check

to the amount of one monthly salary for every two years of service. Three million francs were given by the Solvay Works to the Workingmen's Pension Fund, so that every workman, after 30 years work with the company, now receives a minimum yearly pension of 720 francs (\$144.) Further, every workman will have in future eight days' vacation with pay during the year. Two hundred and fifty thousand francs were donated to the Workmen's University in Charleroi, 500,000 francs for prizes to be awarded by the International Congress of Hygiene, 500,000 francs were given to the chemical laboratory of Paris University, 500,000 francs to Nancy University for a new chair of electrical engineering, 300,000 francs to the hospitals of Ixelles, a suburb of Brussels, 100,000 francs were donated for fighting tuberculosis in Belgium and 75,000 francs for charity work in the little Belgian towns in which the Solvay works are located.

The German Solvay works have donated 3,500,000 marks for their Workingmen's Pension Fund. They also grant to their workmen a vacation of eight days per year with pay and have finally granted 250,000 marks for a scientific prize which is to bear the name of Ernest Solvay.

Russian Heavy Chemicals

(Special Correspondence from St. Petersburg.)

Under the inspiration of the protective policy, which is the governing fiscal policy of Russia, several branches of the chemical industry have been made remarkably successful, the leading ones being the various soda and caustic soda factories. There is little new to be noted with regard to soda in Russia recently. The business, as is known, has developed to such an extent as to make Russian consumers quite independent of foreign sources of supply. This, however, is a luxury which is not particularly relished by the soda consumers, who find that for want of competition they have to pay an enormously higher price to the home producer than they would have to pay to the foreigner were the products of the latter admitted into the country duty free. But that is an old as well as a present-day story. It applies to all countries and need not be insisted on.

It is interesting, however, in connection with this situation, to state on behalf of the soda producers of Russia that whatever their motive may be, the price of soda in the country has been repeatedly reduced lately, so as to respond to a well-sustained agitation on the part of the consumers. As has previously been pointed out, a reduced price which stimulates an increased consumption reacts as a rule in favor of the producer, and figures have already been published and circulated showing that up till the beginning of this year, at all events, that policy had been a very successful one. So successful, indeed, has it been proved to be since these returns were issued that the demand, after having been about equal to the supply, has again outstripped it. The producers, however, anxious to keep control of the market have combined together for the purpose of erecting a fresh large soda factory to meet not only the present increased demands, but also the prospective ones over the next few years, and doubtless they will be successful in maintaining a fair equilibrium between supply and demand in Russia for some years to come with the aid of the new plant to be erected.

It is like repeating what is already world-wide knowledge to say that in bleaching powder, too, the Russian production has come to be quite equal to the demand and under the guidance of such houses as Solvay and Uschloff, etc., it may be relied on to relieve Russian bleachers of all need to apply to foreign chemical works for supplies.

It is a strange thing in connection with the soda branch of Russian chemistry, which has developed so remarkably and so satisfactorily, that the production of salt in Russia should have progressed with very indifferent speed. It might almost be called a stationary industry, particularly if we take into account the immense strides the population of Russia is making in point of numbers and the naturally great increase there must

be in the demand for salt, even for domestic purposes. However, this is the fact. Certain of the salt fields are held to be strangled simply by the syndicates that have been formed to work them, as it was said, in consonance with the demand of Russian industry and the Russian householder. It is possible, though not likely, that a large quantity of salt produced escapes registration, and that the industry may be much larger than represented in official figures; but such is exceedingly unlikely. The suggestion simply arises because of one's inability to explain how it is that such an important essential industry as salt production, should be of such slow growth in a country where the population increases by leaps and bounds, where salt is abundant and where the development of industry, including heavy chemicals, has been extremely active over the last five or six years.

One need only make a cursory reference to the artificial fertilizer industry which has grown very rapidly, but by no means so rapidly as the awakened industrial conscience of the Russian farmer might have led one to expect. If the production at home is proceeding at a much greater rate than before, so is the importation movement, and as the Russian farmer realizes more and more the advantages to be gained from the use of fertilizers, it is obvious that the immense grain and root-growing area of Russia will call for far greater supplies of fertilizers than the home factories can hope to produce, excepting to the extent of, let us say, a fractional supply. It certainly will not be due to Russian chemical enterprise if the home production should increase very largely. It is an enigma, indeed, that in a country like Russia where great chemists are not scarce and where natural resources are not few, with an enormous demand, not at its own doors, but inside its own walls, the fertilizer industry, after a good many years of existence, should not have got beyond the initial stage or little better. It is frequently pointed out, and with reason, that although the raw material is there, it is not quite convenient for manufacturing purposes; but it strikes a student of national and international economics that if the German or English races had been the inhabitants of Russia the phosphates and pyrites of that country had long ago been turned to much better account than they are to-day.

Allied to the fertilizer business, of course, is the industry of coal coking which is extending so rapidly in the South—that is, in the Donetz basin, where the main iron industry of Russia is now located. The coking ovens there equipped with by-product recovery apparatus that might have been counted practically on the fingers of both hands a few years ago, now number thousands and the result is, it need not be pointed out, a relatively large supply of ammonia, which, with sulphuric acid (either produced at home or imported) is converted into sulphate on terms, however, that do not now very strongly tempt the South Russian farmer. Perhaps when he learns to count better he will appreciate its value and not judge it altogether by its invoice cost.

The significance, however, of the by-products recovery in South Russia extends beyond the field of fertilizers and comes closely into touch with the production of finer goods in the form of colors, etc. Time and again word has gone round that companies have been formed for the purpose of establishing factories to extract the more valuable elements from the by-products of the coking ovens, and one or two such have been established; reports on which, however, are exceptionally scarce, and are by no means sufficiently exhaustive to enable one to judge whether the higher chemical industries have got a hold on South Russia or no. One is sometimes led to the suspicion from the reports issued, that the results come rather from the laboratory of the works than from the industrial plant. All the same the raw material is there in increasing quantity; for all the records in coal production in South Russia have been easily broken both last year and this, as also of coke production. There must consequently be a great volume of valuable raw material recovered by the coke makers on which the more complicated chemical industries might easily rest.

From past experience one cannot hope that any immediate

or proximate development of the chemical industry in Russia will result from Russian initiative. Anything that is done in that way will almost certainly be done by German chemists, who have developed from their point of view an excellent system of capturing the Russian market; namely the flotation of Russian companies with a predominating German financial element, for the purpose of constructing in Russia what are euphemistically termed Russian chemical companies; but which in reality are simply manufacturing branches of leading German chemical works.

Manufacture of Aluminium in France

An interesting summary of the present status of the manufacture of aluminium in France is given in *La Revue Electrique* of September 5, 1913.

Five French companies produce aluminium. These are the Société Electrométallurgique Française, the Compagnie des Produits Chimiques d'Alais et de la Camargue, the Société des Forces Motrices et Usines de l'Arve, the Société des Produits Electrochimiques et Electrométallurgiques des Pyrénées, and the Société d'Electrochimie.

These five companies have formed another company, *L'Aluminium Français*, which acts not only as sales agent but is also intended to carry out research work on the applications of aluminium and to devote itself to a propaganda to encourage greater consumption of aluminium. This company also manufactures in its plants at Selzacte, Belgium, and Mennessis. France, considerable quantities of alumina, sulphate of aluminium, etc. It is now erecting at Arrean, in the Pyrenees an aluminium factory and at Chambéry in Savoy, a rolling mill for manufacture of aluminium sheets, etc. At Kremlin-Bicêtre, near Paris, it has a factory for making tubes, etc.

The present status of the five constituent companies is briefly as follows:

Société Electrometallurgique Française.—This is Dr. Paul Héroult's company, formed in 1888—the "dean" of the French electrometallurgical companies. Its capital is 15,500,000 francs (\$3,100,000). In the different plants of the company at Froges, La Praz, Saint-Michel-de-Maurienne, and L'Argentiere (Briançon) 65,000 to 70,000 hp are available during the greatest part of the year. Besides aluminium ingots, bars, wire, cables, tubes, aluminium cooking utensils, and pure alumina, the company produces ferro-alloys, electric steel (Héroult process), and carbon electrodes.

Compagnie des Produits Chimiques d'Alais et de la Camargue.—This company was founded in 1855 and its capital is now 10,500,000 francs (\$2,100,000). Its plant at Salindres (Gard) was originally intended to manufacture soda by the Leblanc process, was later devoted successfully to chlorine manufacture, and began in 1861 to produce aluminium by the purely chemical process of Henri Sainte-Claire Deville. For 30 years it was the sole producer of aluminium. In 1897 it bought the Calypso aluminium plant and later equipped another hydroelectric plant, now producing "considerable quantities" of aluminium.

Société de Produits Electrochimiques et Métallurgiques des Pyrénées.—Founded in 1906, this company has now a capital of 6,000,000 francs (\$1,200,000). Its Ausat plant has a capacity of 16,000 hp and its output is 6 tons of aluminium, 9 tons of chlorates or perchlorates, and 10 tons of calcium carbide or ferro-alloys.

Société des Forces Motrices et Usines de l'Arve.—Founded in 1895, this company has now a capital of 4,100,000 francs (\$820,000). Its Chedde plant has a capacity of 22,000 hp and its maximum output is 6 tons of aluminium and 20 tons of chlorates and perchlorates per day.

Société d'Electrochimie.—This company was founded in 1889 by H. Gall and A. de Montlaur for the electrolytic production of potassium and sodium chlorates and has now a capital of 10,000,000 francs (\$2,000,000). In its numerous plants the company produces chlorates, aluminium, calcium and calcium hydride, sodium, and potassium and sodium cyanides and other chemical products.

Quantitative Spectrum Analysis

III—Industrial Application

By G. A. Shook

We have already considered some of the typical forms of colorimeters and spectrophotometers which may be used for the determination of the concentration of a colored solution, and we will now take up in detail the method of determining the constants necessary for the calculation of concentrations.

The theory of the colorimeter is so simple that it requires no special detailed study, but with the spectrophotometer the case is quite different.

As the essential points can best be brought out by concrete examples we will consider at length some data obtained on simple solutions like copper sulphate and cobalt chloride by means of one of the more complicated instruments, for instance, the Koenig-Martens polarization spectrophotometer. Salts of these solutions may be quickly and easily made up, and they are, therefore, good material for practice work.

A thorough knowledge of a particular instrument, combined with a little manipulative skill in using it, is almost indispensable for the execution of a complicated problem in colorimetry and such experience may be most easily obtained by beginning with the simplest cases.

The data used in this paper is obtained from observations made either by the writer or students of his laboratory, and may give some idea of the accuracy obtainable with limited experience.

Calibration of a Koenig-Martens Polarization Spectrophotometer

There are three general methods which may be used to calibrate a spectrophotometer, and the choice of either must be determined by the conditions under which the instrument is to be used.

(1) When only a rough estimation of the concentration of a solution is required and when only a few samples of the particular substance are to be examined, then it is sufficient to make up a solution of known concentration and to determine the corresponding extinction coefficient for some definitely chosen color.

The absorption ratio may then be calculated, by means of which an unknown concentration may be readily determined.

Consider a special case: A 10 per cent solution of copper sulphate gave a reading on the Nicol scale of 43.2° ($43^\circ 12'$) when the reading of the observing tube was 3.045. The color corresponding to this arbitrary number is green.

The extinction coefficient is therefore

$$e = \log \cot \phi = \log \cot 43.2 = 0.027$$

and the absorption ratio is

$$A = \frac{c}{e} = \frac{10}{0.027} = 370.$$

A 25 per cent solution gave a reading of 40.4° , and its extinction coefficient is therefore

$$e = \log \cot 40.4 = 0.070.$$

Hence the concentration by the optical method is

$$c = Ae = 370 \times 0.070 = 25.9 \text{ per cent.}$$

(2) If an accurate determination is required, then it is preferable to make up several solutions, varying in concentration over a range that will include all the concentrations of the unknown solutions.

Suppose, for example, that the samples to be tested range in concentration from 1 per cent to 5 per cent, then it is well to make up five solutions of 1, 2, 3, 4, 5 per cent concentration respectively, or, if they range from 10 per cent to 50 per cent, make up five solutions of 10, 20, 30, 40, 50 per cent concentration respectively.

The absorption ratio may then be determined for each of the five solutions and the mean may then be used for subsequent calculations.

The data of Table I was obtained from copper sulphate, the results being plotted in Fig. 1.

TABLE I.—OBSERVING TUBE 3.440 (RED) CuSO_4 (DILUTE)

Concentration in %	Rotation of Nicol ϕ	Extinction coefficient e	Absorption ratio A
0.25	42.8	0.033	7.58
0.50	40.5	0.069	7.25
0.75	38.7	0.096	7.81
1.00	36.6	0.129	7.75
1.25	34.1	0.169	7.47
1.50	32.2	0.201	7.50
1.75	30.0	0.239	7.33
2.00	28.1	0.272	7.37

Mean A , 7.51

Now, if we calculate, by means of the average value of A determined from the above data, the concentration of the solution made up to 2.00 per cent we obtain

$$c = Ae = 7.51 \times 0.272 = 2.02 \text{ per cent.}$$

This represents an average accuracy, and if we consider the 0.75 per cent solution whose absorption ratio deviates farthest from the mean, we obtain the following value for its concentration:

$$c = 7.51 \times 0.096 = 0.72 \text{ per cent.}$$

In all of these numerical examples, the concentration of one of the standard solutions is calculated by means of the average value of A merely to illustrate the method and to give a general idea of the accuracy obtainable.

Instead of taking the mean of the five values of A , for subsequent calculations, we may plot e against c on cross-

FIG. 1.—CALIBRATION CURVE FOR COPPER SULPHATE

section paper. Such a curve is shown in Fig. 1. The data used in plotting this curve was obtained from Table I.

According to theory this curve should be a straight line and should, moreover, pass through the origin of the axes, but, of course, all the points will not lie on a straight line due to unavoidable experimental errors. If the departure from a straight line is not greater than might be expected we may assume that Beer's law holds for the particular substance, at least for the range of concentrations chosen.

As long as this linear relation obtains, we are not concerned, at least in practice, about the ultimate cause of the color; that is, whether it is due to the molecule, the positive ion or the negative ion.

When such a curve is once constructed, then for future work it is only necessary to set the observing tube to 3.440 and to obtain the reading of the Nicol for the particular solution in question. If the log cotangent of this angle is obtained from a table, then the concentration may be read directly from the calibration curve.

(3) A third method is to construct a table giving the concentration corresponding to every circular degree on the Nicol scale. In this way any calculation whatsoever is avoided, it being only necessary to determine experimentally the angle of rotation of the Nicol, such that a photometric balance is obtained for the particular solution.

This expedient is justifiable whenever a large number of samples are to be tested. The greater the accuracy required the greater must be the number of standard solutions made up. Portions of such a concentration table, which were con-

structed from the above data upon copper sulphate are given in Table II.

TABLE II.—OBSERVING TUBE 3.440 (RED).
CuSO₄ 10 mm. cell

ϕ	c	ϕ	c
20	3.29	31	1.66
21	3.12	32	1.56
22	2.95	33	1.40
23	2.78	34	1.28
24	2.63	35	1.16
25	2.48	36	1.06
26	2.34	37	0.92
27	2.19	38	0.80
28	2.06	39	0.69
29	1.94	40	0.57
30	1.79		

This table was constructed as follows: Take, for instance, the first angle 20° , $\log \cot 20 = 0.439$, hence

$$c = Ae = 7.51 \times 0.439 = 3.29.$$

Now, if a copper sulphate solution of unknown concentration produces a reading of 30° on the Nicol scale, its concentration is found directly from the table to be 1.79 per cent.

The best color, or wave-length of light, to use may be determined experimentally, if more than one standard solution is made up. If the solution is blue, then it will absorb more red light than blue light and consequently the red part of the spectrum should be used, provided that the sample is not too concentrated.

For if it is very dilute the blue part of the spectrum cannot be utilized, since the rotation of the Nicol, ϕ , necessary to produce a balance, will be so small that an accurate value of the extinction coefficient cannot be obtained.

If it is very concentrated too much light will be absorbed in the red and consequently a good balance cannot be made.

These effects are shown in a striking manner by means of the following data obtained from a blue salt, copper sulphate:

Weak Blue Solutions (CuSO₄).
Observing Tube 3.440 (Red).

CONCENTRATION IN PER CENT, c .				
0.25	0.50	0.75	1.00	1.25
ROTATION OF NICOL, ϕ .				
42.8	49.5	38.7	36.6	34.1

This gives a fairly wide variation of ϕ , so that accurate results may be obtained. For high concentrations the absorption in the green was found sufficiently great, as is shown by the following data:

Strong Blue Solutions (CuSO₄).
Observing Tube 3.045 (Green).

c 10	15	25	30	45
ϕ 43.2	42.1	40.4	38.6	36.9

In like manner for weak red solutions one cannot employ the red part of the spectrum, as is seen from the following results:

Weak Red Solutions (CoCl₂).
Observing Tube 3.540 (Red).

c 1	2	3	4	5
ϕ 43.6	42.6	42.1	41.5	40.7

The difference in the reading of the Nicol in this case is obviously not sufficient for accurate work.

The green part of the spectrum was then used for the same solutions with the following results

Weak Red Solutions (CoCl₂).
Observing Tube 3.000 (Green).

c 1	2	3	4	5
ϕ 41.5	35.6	31.9	27.7	22.9

However, for strong solutions of cobalt chloride the red part of the spectrum is best adapted, as shown in the following table:

Strong Red Solutions (CoCl₂).
Observing Tube 3.540 (Red).

c 10	15	20	25	30
ϕ 37.4	35.7	32.9	30.6	27.9

To determine the best position of the observing tube, fill the cell with the weakest solution and obtain a rough balance in different parts of the spectrum, noting the reading of the observing tube for each position. Repeat the same operation with the strongest solution and then choose the position of the observing tube which gives the greatest change in the reading of the Nicol for the two solutions.

What has been said in regard to calibrating the Koenig-Martens instrument may be applied to any spectrophotometer. In the case of the double-slit instrument, one is concerned with the width of a slit and not with the rotation of an analyzing Nicol. Consequently the expression for e will be different.

For work where extreme accuracy is not required the polarizing instrument has this decided advantage over other types, namely, that the relation between the log cotangent of the angle made by the analyzer and the angle itself is approximately linear at least from 45° down to 25° . This simply means that instead of looking up the log cotangent of ϕ , each time, we may simply use ϕ .

To illustrate, the data obtained on copper sulphate, Table I, was used to plot a curve with c and ϕ as coordinates and it is seen from Fig. 2 that the points lie on a straight line which passes through 45° , where the concentration is zero, as would be expected, for if the concentration is zero the fields are equally bright and therefore the Nicol must make an angle of 45° . The extinction coefficient then assumes the simple form

$$e = 45 - \phi$$

whence

$$c = Ae = A(45 - \phi)$$

and

$$A = \frac{c}{45 - \phi}$$

The absorption ratios for the various concentrations are given in Table III.

TABLE III.	
Concentration in Per Cent.	Absorption Ratio.
c	A
.25	0.114
.50	0.111
.75	0.119
1.00	0.119
1.25	0.115
1.50	0.117
1.75	0.117
2.00	0.119
Mean A , 0.116	

The 2 per cent solution gives a reading of 28.1 and therefore by this approximate method its concentration is

$$c = Ae = 0.116(45 - 28.1) = 1.96 \text{ per cent.}$$

An inspection of the two curves, Fig. 1 and Fig. 2, will show at once that for the particular data at hand the points obtained by plotting c and ϕ will not deviate from a straight line any more than the points obtained by plotting c and $\log \cot \phi$.

Of course, it is not necessary to plot a curve if one calculates A for each concentration, for if the variation in the values of A is not greater than might be expected from experimental errors then the exact method need not be resorted to.

If the initial balance is not carefully made then A will not be

constant for different values of e , although a straight line may be obtained by plotting c and e . The straight line thus obtained, however, will not pass through the origin.

If it is found that A is not constant for a particular set of standard solutions it is best to plot a curve before concluding that Beer's law does not hold, for the variation in A may be due only to an error in the "zero" reading.

A rule for determining roughly the best wave-length or color to be used when this particular instrument is employed may now be formulated.

Since the entire angular change of the Nicol should be about 20° , the reading on the Nicol scale for any particular concentration may be calculated approximately. Let us suppose we have a range of concentrations extending from 1 to 5 per cent.

It has been shown that

$$c = Ae = A(45 - \phi)$$

and it follows that

$$c/c' = e'/e = c''/c'' \dots = \text{constant.}$$

Now, if $c = 1$ per cent and $c' = 5$ per cent, then since the reading of the Nicol for the 5 per cent solution should be

FIG. 2.—CALIBRATION CURVE FOR COPPER SULPHATE (APPROXIMATE METHOD)

about 25° , the reading for the 1 per cent solution must be about 41° for

$$c/c' = 1/5 = (45 - \phi)/(45 - 25)$$

or

$$\phi = 41^\circ.$$

Hence, for the five concentrations, the corresponding readings on the Nicol scale must be approximately as follows:

CONCENTRATION IN PER CENT c .				
1	2	3	4	5
READING OF NICOL SCALE ϕ .				
41	37	33	29	25

The method of procedure would be as follows: Fill the cell with any of the five solutions, say the 3 per cent solution, and set the Nicol to 33° . Now, rotate the observing tube until an approximate balance is effected and note the reading of the observing tube scale.

For example, five concentrations of potassium permanganate were made up as follows: 0.01, 0.02, 0.03, 0.04, and 0.05 per cent. In order to make an approximate balance for the 0.03 per cent solution, it was necessary to move the observing tube to 3.400 (red) when the Nicol was set at 33° .

The following readings were then obtained for the five solutions:

CONCENTRATION c .				
0.01	0.02	0.03	0.04	0.05
READING OF NICOL SCALE ϕ .				
40°	35.8	32.5	28.5	25.1

This general method of determining the proper color may always be applied to the Koenig-Martens instrument whatever

method is used to calibrate it. If one wishes only approximate results and makes up only one standard solution, then the best color may be readily found by the above method.

Concentration of Colorless Solutions

The concentration of a colorless solution may sometimes be determined by means of a spectrophotometer if a reagent can be added which will produce a color or which will cause the solution to become turbid.

For example, if a solution of barium chloride is added to a solution of potassium sulphate, a fine white precipitate is formed by the insoluble barium sulphate. Since all the other salts in the solution are soluble and, moreover, colorless, the density of the precipitate, that is, the number of absorbing molecules per c.c. of the absorbing medium is directly proportional to the concentration of the potassium sulphate provided an excess of the barium chloride is added.

As long as the precipitant is colorless and soluble an excess of it merely plays the rôle of a solvent. By means of the spectrophotometer we can get a measure of the absorption caused by the precipitate and hence it is readily seen that such an instrument may be employed for this class of analysis.

When the percentage of potassium sulphate in any unknown solution is once determined, then it is only a matter of calculation to obtain the per cent of SO_4 , S, or O, etc.

In coal analysis we are concerned with the amount of sulphur present, while in water analysis with the amount of SO_4 . We might, of course, add an excess of the sulphate and then determine the percentage of chlorine in barium chloride, etc.

We will now consider a few examples. The average value of the absorption ratio, A , determined from three solutions of potassium sulphate was 0.0577. The solutions were made up to 0.02, 0.01 and 0.005 per cent of SO_4 .

For the solution made up to 0.005 per cent the extinction coefficient was found to be equal to 0.089 and, therefore, the optical method gives, for its concentration,

$$c = Ae = 0.0577 \times 0.089 = 0.00512 \text{ per cent}$$

In the same manner data was obtained for the determination of the percentage of chlorine in sodium chloride. A silver salt was used as a precipitant. In order to keep the precipitate in suspension long enough to make the necessary readings rather dilute solutions had to be used. The following data was obtained:

Estimation of Cl in NaCl by means of the absorption of AgCl.

Concentrations based on the per cent of Cl.

c	0.0570	0.0429	0.0286	0.0143
ϕ	38.5	40.6	42.2	43.8

The average value of A from the above table is 0.651.

For the 0.0286 per cent solution the optical method gives the following results:

$$e = \log \cot 42.2 = 0.043$$

and therefore

$$c = Ae = 0.651 \times 0.043 = 0.028 \text{ per cent Cl}$$

We may consider one more example of a similar character, namely, the estimation of calcium in calcium chloride (Table IV). In this case ammonium oxalate is added to the calcium chloride solution and the absorption of the insoluble calcium oxalate is taken as a measure of the concentration of the calcium.

This is a good example of the ability of such an instrument to detect the presence of very small quantities. The concentrations are based upon the per cent of calcium

TABLE IV.—ESTIMATION OF Ca in CaCl.

c	ϕ	c	A
0.00125	42.4	0.030	0.0320
0.00250	30.0	0.002	0.0272
0.00500	33.4	0.181	0.0362
0.01000	24.2	0.347	0.0289
Mean A , 0.0311			

The concentration of the 0.01 per cent solution is from the above value of A :

$$c = Ae = 0.0311 \times 0.347 = 0.0108.$$

The estimation of iodine in potassium iodide is a good example of the determination of the concentration of a colorless solution (Table V).

Iodide of potassium is colorless, and in order to develop a color a reagent was added which would liberate the iodine and not produce an additional color. Dilute nitric acid was used in this case. We might use $K_2 C_2 O_7$ to liberate the iodine, but this reagent gives an additional color. Alcohol was also added to hold the liberated iodine in solution.

TABLE V.—ESTIMATION OF I IN KI.
Concentrations based on per cent of I.
Observing tube 3.000 (Green).

c	ϕ	e	A
0.25	20.5	0.427	0.586
0.125	31.4	0.214	0.585
0.0625	37.1	0.121	0.516
0.0313	39.7	0.081	0.387
0.0156	42.4	0.039	0.402

The data of Table VI upon resublimed iodine dissolved in alcohol is given to show the systematic variation of the absorption ratio A . This change in the value of A is probably due to the oxidation of the iodine into hydriodic acid which is colorless.

Beer's law evidently does not hold in this case and accurate results could not be obtained except for a limited range of concentrations.

TABLE VI.—ESTIMATION OF IODINE IN ALCOHOL.
Observing Tube 3.000 (Green).

c	ϕ	A
0.25	18.8	0.535
0.125	29.5	0.507
0.0625	35.9	0.446
0.0313	39.4	0.367
0.0156	41.9	0.331

The absorption ratio A can almost always be determined by means of data obtained from controlled experiments. For instance, in order to determine the percentage of P_2O_5 in a sample of fertilizer it is not necessary to have a number of samples of fertilizer in order to determine A . This may be illustrated by an example.

The following method of preparing the solutions and the sample of fertilizer to be tested is due to Professor Spitzer, of Purdue University, who has perhaps done more work in colorimetry than any other chemist in this country.

The solutions were prepared from a standard solution of calcium phosphate. The phosphate was first precipitated as ammonium phosphomolybdate. This insoluble precipitate was then washed with dilute nitric acid, to free it from the soluble ammonium phosphomolybdate, and finally dissolved in a dilute solution of potassium hydroxide.

Hydrogen sulphide gas was then passed through this solution, causing it to turn to a clear yellow color. The color depends upon the concentration and it varies from yellow to brown. This solution was then diluted according to the percentage of P_2O_5 required. The data for six different concentrations of P_2O_5 is given in Table VII.

TABLE VII.—ESTIMATION OF P_2O_5 AS MOLYBDIC SULPHIDE.

c	ϕ	e	A
0.00078	44.1	0.014	0.0557
0.00156	42.0	0.046	0.0340
0.00312	40.1	0.070	0.0445
0.00623	35.6	0.145	0.0430
0.0125	28.8	0.260	0.0480
0.02500	17.5	0.502	0.0499

Mean A , 0.0459

A sample of fertilizer secured from the Agricultural Experiment Station was made strongly ammonical and then a slight excess of nitric acid was added according to the directions of the official methods of analysis.

This solution was heated to about $80^\circ C$. and an excess of ammonium molybdate solution was then added and the heat continued for an hour.

The precipitate, phosphomolybdate of ammonia, was then collected on a filter and well washed with dilute nitric acid to free it from any traces of molybdate solution.

It was next dissolved in a boiling solution of 5 per cent potassium hydroxide. Sulphurated hydrogen was then passed through this solution for twenty minutes, causing it to assume a deep red color due to the formation of the molybdate sulphide.

The solution gave a reading of 30° on the Nicol scale, whence its extinction coefficient is

$$c = \log \cot 30 = 0.239$$

and its concentration is

$$c = Ae = 0.0459 \times 0.239 = 0.0110.$$

But 125 c.c. of the original solution represents 1 gram of fertilizer, hence the per cent of P_2O_5 in the fertilizer is

$$c = 125 \times 0.0110 = 1.37 \text{ per cent.}$$

The value obtained by the station was 1.51 per cent. Professor Spitzer has carried out a number of such determinations and his average error is considerably less than this.

It is sometimes more convenient to use actual samples for making up standard solutions than to attempt to make, as it were, artificial standards. For instance, in the determination of the per cent of combined carbon in steel by colorimetric methods, one can obtain from the U. S. Bureau of Standards samples of steel which have been accurately analyzed by chemical methods. These samples range in carbon content from a few tenths of 1 per cent up to several per cent.

We will now consider at length a practical example. A 1 per cent solution of iron was made from a sample of malleable iron containing 3.40 per cent of combined carbon. This solution was then diluted so as to make four more solutions of different concentrations. Data was then obtained upon these five standard solutions by means of a Lummer-Brodhun spectrophotometer of the ordinary form.

The importance of an accurate initial balance is clearly brought out by the first set of data obtained upon these iron solutions.

Both slits were set at 30 and a cell containing water was placed in front of one slit. The lamps were then adjusted until the two photometric fields appeared equally bright and without making any further check upon this balance both slits were opened to 100. The data given in Table VIII was then obtained.

TABLE VIII.—ESTIMATION OF CARBON IN IRON.
Concentrations based upon per cent of iron.
Observing tube 72.0 (Green).

c	R	e	A
.125	58.0	0.229	0.546
.250	51.0	0.292	0.857
.500	43.0	0.365	1.37
.750	33.6	0.474	1.58
1.000	27.0	0.567	1.77

R is the reading of the slit and therefore

$$c = 2 - \log R.$$

One might infer, at first sight, that Beer's law does not hold in this case, since A varies continuously.

If, however, c is plotted against e it is readily seen that a linear relation obtains, hence we may infer that the law does hold.

The cell filled with water, was again placed in position and an accurate balance was obtained by adjusting the slit which was not covered by the cell. The average reading of the slit was found to deviate considerably from 100, as might be expected.

It was then set at 100 and the other slit (i. e., the one covered by the cell) was carefully adjusted until a balance was effected.

To make sure that the balance was accurate the first slit was again reset a number of times and the average reading was found to be 99.88. The other slit, which read 125.2, was left intact and the data of Table IX was obtained upon the same solutions.

TABLE IX.

c	R	e	A
0.125	88.9	0.051	2.45
0.250	76.4	0.117	2.14
0.500	62.9	0.201	2.49
0.750	50.0	0.301	2.49
1.000	38.0	0.420	2.38

It is seen from the above table that the variation in A is not more than might be expected from experimental errors.

The second solution, 0.25 per cent, was slightly turbid, consequently its absorption ratio A is too low and it should, therefore, not be considered in determining the mean A .

The data of Table X, for the determination of the per cent of sulphur was also obtained by means of the same instrument.

Barium sulphate was precipitated from a solution of potassium sulphate by adding an excess of barium chloride. Due to the rapid precipitation of the barium sulphate only a few readings can be obtained before the solution becomes non-homogeneous.

If the cell is shaken and then allowed to stand a few seconds the solution will again become homogeneous and the readings may be repeated. In this manner it was possible to obtain fairly consistent results.

TABLE X.—ESTIMATION OF SULPHUR AS BARIUM SULPHATE.
Concentrations based upon per cent of sulphur.
Observing Tube 72.0 (Green).

c	R	e	A
0.005	69.9	0.155	0.0323
0.010	55.3	0.257	0.0389
0.015	32.5	0.488	0.0307
0.020	28.3	0.548	0.0366

Mean A , 0.0346

It is thus seen, from these few examples, that any first-class spectrophotometer may be universally used for the determination of the concentration of a colored or turbid solution.

University of Illinois,
Urbana, Illinois.

The Leadville Pumping Association, organized to unwater the mines of Fryer hill, Leadville, announces that it has obtained signatures from over 85% of the owners of Fryer hill ground, agreeing to the terms of the proposed scheme of unwatering and operating the mines.

The International S. & R. Co. now has five blast furnaces in operation on lead ore at the Tooele plant. A feature of construction of furnaces at this smelter is the use of two rows of jackets, the advantages of which are that accretions are less likely to form, and are more easily barred when they do form.

Commercial Relations of the United States.—A concise volume, which contains statistics showing the foreign trade of each country of the world during 1911 compared with the previous year, has just been issued by the Bureau of Foreign and Domestic Commerce at Washington. It shows the principal articles and their value entering into the trade of each country and gives itemized figures for the imports from and exports to the United States. The statistics were prepared by American consular officers, and supplemented by other official data. In addition to trade statistics, the grain crops and mineral output of the principal countries are given, thus presenting in compact form the principal features upon which the commerce and industries of the foreign countries depend. Copies of the book may be obtained from the Superintendent of Documents, Washington, D. C., for 35 cents each.

Condensation of Zinc Gas to Liquid, in the Presence of Inert Gas.

By F. L. Clerc

The difficulty in collecting distilled zinc in the liquid state, reported by numerous experimenters with new furnaces, indicates that the problem of condensing zinc from a gas to a liquid, in the presence of inert gases, is one of general interest. The zinc obtained has been solid, in the form of powder, and more or less oxidized. It is usually described as "blue-powder." In a former paper I have shown how indefinite this term is, and how important it is that there should be a more exact classification of the various products. Some zinc in solid powder is produced in all industrial zinc furnaces, and it is not probable that any furnace can be designed which will entirely avoid its production, or will reduce it to negligible proportions.

The problem of immediate interest is, to get as much of the zinc in the liquid state as possible; and, what is quite as important, to prevent the zinc dust, which is invariably formed, from obstructing the apparatus and interfering with or even putting a stop to the operation. The rapidity with which zinc gas is evolved by some furnaces, is given as a reason why the zinc is not collected from them as a liquid. It is probable that apparatus could be devised to effect condensation in spite of a rapidity of volatilization far exceeding that observed in any furnace working on an industrial scale, if uniformity in the rate of volatilization could be attained. That is, we should rather modify the relative size of condensers, than restrict the rate of distillation to conform to present practice. The real difficulty comes from the irregularity, and not from the rapidity, with which zinc gas is evolved.

It has been generally known for a long time that both chemical and physical causes contribute to the formation of zinc dust. Mr. W. McA. Johnson has proposed the names "physical" blue-powder and "chemical" blue-powder, to distinguish forms of different origin. The suggestion has value, if only to keep in mind the joint action of both chemical and physical forces. If he will still further inform us how these two forms can be distinguished, one from the other, and whether he has observed intermediate forms, he will furnish criteria by which we can diagnose the cause of any particular failure, by examining the blue-powder produced.

The Effect of Oxidation

In the meantime, admitting that both chemical and physical causes often act together, it may be well to consider them separately. The chief chemical cause assigned for the formation of blue-powder is oxidation. But there is a great variation in the amount of oxide present in different samples of commercial blue-powder, and it is difficult to know with certainty that oxidation has not occurred after the blue-powder has formed; that is, during its removal from the condenser and prior to the analysis. If it is argued that the least amount of oxide present in commercial samples is sufficient to account for the formation of the powder, and that greater amounts found in other samples were formed after solidification, this question can be tested by experiment.

In the sample of blue-powder mentioned in my former article, referred to above, which was melted in a Berzelius arsenic bulb, there was evidently not enough oxidation to prevent coalescence. Moreover, Dr. E. Haanel has informed me that he has melted tons of blue-powder, after mixing it with carbon in proper form and amount. It is not probable that any zinc oxide was reduced in this operation. The explanation is that the air between the dust particles acted on the carbon at about the temperature of melting zinc, forming carbon monoxide which prevented further oxidation of the zinc. Evidently, then, there was not sufficient oxide present originally to prevent melting the blue-powder. Some other contributing cause than oxidation must, therefore, be found for the formation of blue-powder. The question arises: Is it possible by chemical analysis to determine what amount of oxidation will

prevent coalescence, or to devise some other test to distinguish "chemical" from "physical" blue-powder?

The oxide formed, being lighter than the metal, is supposed to float on the surface of the liquid globules, and, when present in sufficient amount, to form a protective coating over them. It is interesting to consider how the amount of oxide required to form a protective coating over all the surface of the globules, will vary with their size. The volume of a given weight of liquid zinc is the same, other conditions being equal, whether it exists as one sphere or any number of spheres; but the combined surface of the smaller spheres will exceed the surface of the single sphere. It follows that an amount of oxide just sufficient to paint a single sphere, will not effectively cover two or more spheres, the combined volume of which is equal to that of the larger sphere. Evidently then, if some oxide is present, as condensation progresses in the Belgian condensers and the globules grow by accretion, some size must be reached at which the oxide present is sufficient to form a protective coating. Does this indicate an upper limit to the size of the globules formed, in condensing zinc gas in the presence of some zinc oxide?

Some plausibility is given to this hypothesis by the rather constant percentage of the weight of commercial blue-powder of widely different origin, which will pass through a 200-mesh sieve. I shall, however, offer a different explanation of this uniformity. Other chemical forces than oxidation may contribute to the formation of blue-powder. The presence of cadmium, arsenic, antimony, tellurium, selenium or sulphur may have some effect; but none of them can be considered as generally acting.

Mechanical Forces Considered

The mechanical forces which may produce blue-powder can be considered under two headings: First, atomic and molecular forces; and, second, mechanical forces.

First: Atomic and Molecular Forces.—The force expressed in heat units required to overcome the atomic and molecular forces which hold zinc in the liquid state, is a direct measure of the force which tends to condense it, for on condensation the same amount of heat is given out. But in order that these atomic and molecular forces can come into play, the separate particles must be brought into close proximity. It has been concisely stated that condensation is essentially a cooling operation; but simple withdrawal of heat will not suffice to bring the particles together to its original liquid state.

Condensation a Complicated Phenomenon

Experiments with liquids which boil at a lower and more easily controlled temperature, show that condensation is a very complicated phenomenon, and that the liquid globules increase rapidly in size after their presence in the gas is indicated by the appearance of a nebular zone. Their formation is assisted by the presence of minute solid particles, called nuclei, throughout the cooling gas, around which condensation occurs. When they attain a certain size they fall by gravity at a measurable rate, and collect as a liquid mass at the bottom of the containing vessel. The walls of this vessel act similarly to the nuclei, and doubtless the nature of the walls and of the liquid have some effect.

It is reasonable to suppose that zinc gas in condensing behaves similarly; and that for a complete explanation of condensation we must have a perfect understanding of the laws of diffusion, viscosity, and vapor tension of gases, and of the surface tension, capillarity, adhesion and cohesion of liquids; for all of these forces are involved, either in the collection of liquid globules on the walls of the condenser, or in their union with the liquid mass. Some of them have to be overcome in the operation of condensation; others assist it. As examples of coalescence, distinct from condensation, we may cite the gathering of scattered globules of mercury; the coming together of rain drops on a window pane; and the rolling of drops of water over a wave surface of a larger mass of water, particularly if the latter be salt or muddy, before they merge themselves into the greater mass.

It is fortunate that we do not have to take account of all of these forces, the laws of which are but little known, for the reason that we know they act when the particles are brought close enough together, and that they always act the same way under the same circumstances. Furthermore, we know that a large percentage of zinc gas condenses itself into a single liquid volume, in the small space of a Belgian condenser, and within the very short time it takes the accompanying gas to traverse it.

Effect of Gravity and Mass Action

Second: Mechanical Forces.—The extraneous forces which I shall consider as acting on the zinc globules and accompanying gas, which are to be relied on to bring the zinc atoms and molecules into such proximity that intermolecular forces can come into play, are gravity and mass motion. The action of these forces, while not more mechanical than the action of any physical force, is subject to well-known mechanical laws. Mass motion is due to change of volume by the addition or subtraction of heat; that is, by change of temperature, or change of state accompanying volatilization or condensation.

Gravity, of course, is constant; but it is opposed by several resistances. Here is not a case of bodies falling or moving through a vacuum. The solids and liquids fall through a moving fluid, the density of which varies with the temperature. The surface friction of the globules and the viscosity of the fluid all oppose motion. This opposition, however, is not directive; its effect is simply to lengthen the time required to traverse a given space.

In designing a condenser, we can extend indefinitely the time during which condensation is possible, and thus allow time enough for gravity to perform the same work in a large condenser which it accomplishes in the Belgian condenser. Likewise, in the motion produced by change of volume, we need not consider opposing forces; a time allowance can be made. The relative direction and velocity of these two motions determines the path of the globules, and brings them together against obstructing surfaces. The importance of a uniform current of gas, in a direction favorable to bringing the globules within the range of action of molecular forces, is thus very strongly in evidence. Whatever may be the rate of evolution of zinc gas, the condenser may have a cross-section to give a proper velocity and direction to the issuing gas current.

Range of Temperature Unalterable

There is, however, one condition which cannot be varied, whether the condenser is large or small, and that is the range of temperature within which condensation is possible. The condenser must be kept at a temperature between the melting and boiling points of zinc, and the gases should cool gradually from their entrance to their exit. It is readily admitted that such close regulation is much more difficult in the case of a large condenser than of a small one. In the case of the Belgian condenser, more than enough heat is carried in by the gases to maintain this temperature under normal working conditions. The same proportion of heat should be supplied by the gases to a large condenser. The Belgian condenser receives heat from the front of the furnace, and radiated heat from the open mouth of the retort. Both condensers lose heat by radiation. A rapid and uniform rate of distillation should lessen the percentage loss from this source. In this connection, also, it must be remembered that the ratio of the surface to the volume is much smaller in the case of a large condenser than of a small one. The effect of these different conditions is to offset each other to some extent. But if the loss of heat in the large condenser is too rapid or too local, precautions must be taken against this, and if necessary, external heat must be applied. This is no more irrational than is the reverse operation of cooling furnace walls with air and water-jackets.

The problem of regulating the temperature of a condenser resolves itself into three simple problems: First, getting it hot enough at the start; second, conserving the heat during normal working, so that the condenser may be as large as

practicable; and third, supplying or dissipating heat locally as desired. The drawing in Fig. 1 will express these ideas applied to a concrete case. It is a condenser designed for use with a copper-bottom retort working continuously.² This condenser should have in front a removable panel with its own lining, in addition to a removable cover to afford ready access to the interior; and it should be nearly red-hot when it is attached to the retort. I think the cut and references will be readily understood, and that the ideas may be applicable to condensers designed for other forms of continuous zinc furnaces.

Suggested Design of Condenser

The length of this condenser will be equal to the greatest length of the retort, and its capacity will be regulated as nearly

FIG. 1.—ZINC CONDENSER

Washing the Carbon Monoxide Gas

An iron tank, divided near the bottom into eight downward-pointing compartments, each of which has its own discharge cock, is partly closed at the top by an iron cover, the deep flanges of which are notched to fit the sloping sides of the bottom compartments. The gas is led under the cover through three downtake pipes, each of which receives a shower of water drops admitted, above the entrance of the gas, through finely perforated plates, from a tank containing filtered water. This water, rising between the tank and the cover, prevents the escape of gas. The gas under the cover escapes through the small pipes which encircle the downtakes, and is collected in the gas box above. The downtakes pass through sleeves

FIG. 2.—WASHER FOR RETORT CASES

as may be to the normal working of the furnace. The gas issuing from the condenser will be nearly pure CO, and of high calorific value. It will be needed to dry and heat up the condensers, and occasionally to blow the residues out of the retort. It will carry out an amount of blue-powder too important to be lost, and which should be recovered by washing the gas. The washed gas should be carefully stored. Its volume will be relatively small; for each ton of zinc reduced there will be formed 863 lb., corresponding to 10.96 cu. ft. of CO, at standard conditions of temperature and pressure. I can suggest no better washer for this purpose than is shown in Fig. 2, which is reproduced from my Belgian patent of July 26, 1876.

inserted between the top and bottom of the air box. The object of this construction is to get as equal distribution of gas as can be had by axial symmetry. The object of the small tanks is to cool and dry the washed gas, and to return to the tank any fume which may adhere to them. Anyone who has thrown very fine blue-powder into water, hot or cold, knows how quickly it settles to the bottom.

The underlying idea of this washer is to avoid eddies and opposing currents in the gas. The falling drops have the same direction as the gas, and will help to regulate the draft. The top of each downtake can be closed by a sagging disc of rubber, which can be lowered to close some or all of the holes in the perforated plate. The water can thus be shut off instantly. Quickly acting dampers should be inserted in the pipes lead-

²This journal, Aug., 1912, page 463.

ing from the retort, so that the operator can quickly close connection between the condenser and the washer. The washed gas should be stored in a gasometer. No washer will prove satisfactory unless it can be shut off from the condenser as quickly as a gas burner can be turned off. I believe that every one will agree with me that the size of the grains of blue-powder carried out of the condenser is limited by the size of particles of zinc which can be transported by the force of the current at its point of exit.

Estes Park, Colorado.

Gold-Milling Progress in California

By Al. H. Martin

The modern stamp mill was evolved from California practice, but California metallurgists have been the most conservative in adopting methods developed by operators in other fields. Stamp-crushing, amalgamation and concentration on blanket or canvas tables completes the ore treatment in a majority of the leading gold-mining districts of the State, and it has only been within the past five years that the cyanide process has been employed to any extent. But recently a more

month, but no attempt was made to secure a better yield until the present owners took charge.

The new mill embraces twenty 1250-lb. stamps, in place of the twenty 750 and twenty 850-lb. stamps formerly employed. The ore is very hard, silicious, and of high milling grade. The crushed product is trammed to the small mill bin, designed to enable a rapid and accurate measurement of bin contents at any time desired. Challenge non-suspended feeders serve the stamps. The mortars are of the high, rapid-discharge type, weighing 8500 lb. each and mounted on foundations composed of concrete made from selected quartz and granite. These foundations were carefully moulded and have given splendid service. Crushing is done in cyanide solution through Tyler ton-cap screens and the pulp delivered to a Dorr duplex classifier. From this machine the coarse product passes to a 5 by 18-ft. tube-mill, and the slime overflow proceeds to the tanks. The tube-mill discharge is returned to the classifier by a bucket-elevator and the product kept in the circuit until sufficiently fine to pass off in the slime overflow.

Air Lifts Supersede Centrifugal Pumps

From the Dorr classifier the pulp continues to a 20 ft. by 10 ft. Dorr thickener. The slime product from the classifier contains 6 parts solution and 1 of solid, and is thickened to a ratio of 2 to 1. The centrifugal pump at first employed to elevate pulp from the thickener to the agitating tanks has been replaced with an air-lift. This was done because of the excessive wear on the pump by the hard and gritty slime. Six hp. is required for operation, and the air-lift has proven most satisfactory. The three agitating tanks are of the Pachuca type, 10 ft. by 30 ft. They are arranged in such a way that any tank can be passed and eliminated from the circuit without interfering with operations. Air is supplied at 40-lb. pressure to agitators, air-lift and filter department by an Ingersoll-Rand 8 in. by 10 in. standard air compressor.

Lead acetate was formerly added to the solution in agitators and stock tanks at the rate of 30 to 40 lb. per working day; but experiments proving that 24 lb. of commercial litharge produced as favorable results, the latter was used instead, resulting in a marked saving in costs. The litharge is added to the tube-mill and agitators in equal amounts. After agitation the pulp goes to a second Dorr 20 ft. by 10 ft. thickener, the overflow from which proceeds to the collecting tank, and thence is pumped to the clarifying and precipitating department. The underflow passes to the filter. As the ore milled averages \$30 per ton, the pregnant solution is high-grade. In order to reduce the gold content of the pulp passing to the filter, the agitated pulp flowing to No. 2 thickener is diluted with the overflow from No. 1 thickener and barren solution by mixing the \$3 per ton solution from No. 1 thickener with the \$8 product of the agitators, and by the addition of considerable barren solution from the stock tanks. In this way the gold content of pulp passing to the Oliver filter is reduced from \$8 to \$2 per ton. The filtrate is combined with the overflow from

FIG. 1.—DARROW-HAMBLIC SLIME CONCENTRATOR

progressive spirit has developed, with the result that thousands of tons of tailings that were formerly wasted are now yielding good profits, and ores that were deemed too refractory to warrant consideration have become sources of excellent profit. Conservatism still reigns in most of the districts, but the stronger companies are gradually adopting the more advanced methods.

Cyaniding at the Black Oak

As an example of the new era in California gold-milling, the recently erected plant of the Black Oak Mining Co. commands particular attention. It is the first all-sliming cyanide plant ever built in the State, and is located at Soulsbyville, Tuolumne county, in the eastern portion of the Mother Lode gold-bearing zone. The mine has been a heavy producer for years, with attention largely confined to the higher-grade quartz. The old mill contained 40 light stamps, and crushing was followed by amalgamation and concentration with vanners and canvas tables. The extraction was never good and thousands of dollars' worth of high-grade tailings were washed to waste every

No. 2 thickener, and the clarified solution is precipitated in Merrill presses by the customary zinc-dust method. The mill extraction has never fallen below 95% in any month, and at times has exceeded 97%. The daily capacity of the old mill using light stamps, was 66 tons. With the 1250-lb. stamps the capacity has been increased to 100 tons.

Improvements in Concentration

The use of canvas tables in concentration is still favored by a majority of California millmen, but progress in this department of milling is also being recorded. The original California concentrator consisted of a wooden frame covered with bullock hides, supported by stringers to give fair rigidity and strength. Later on heavy carpet and specially woven blankets were employed to arrest the gold escaping the amalgamating plates. The employment of canvas later came into favor, and this material is still largely employed in California concentration. Two distinct types of tables are used: the long and narrow, and the broad and short. The latter is generally preferred, because of the ease with which it is operated, but both types have many advocates. The table that has found greatest favor is about 12 ft. wide by 13 ft. long, provided with short lengths of hose at frequent intervals to facilitate easy washing. The tables are built with an inclination of 1 to 1½ in. per ft., and are constructed of 2 by 8 in. stringers with redwood or pine flooring. No. 7 or No. 8 canvas is generally used. At the larger mills the tables are arranged in a double bank.

In early California practice the pulp from the batteries passed direct to the canvas or blanket concentrator, but the method now favored is the treatment of the pulp on Gates or Frue vanners before passing to the tables. In this way a higher concentration is secured. In the Kennedy mill, one of the largest in California, 40 Frue vanners and 56 canvas tables are employed in concentration.

Latest Type of Canvas Table

The tendency in California concentrating is to secure a clean product at a reduced labor cost, and one of the advantages claimed for the Darrow-Hambrick type of table is that it meets this requirement. This table is the latest type of the California canvas concentrator and embraces several features of interest. In place of the usual canvas covering, asphaltic felt or boards coated with asphalt paint are employed to collect the gold. The tendency in concentration is toward the employment of a finer collecting surface, as shown by the gradual change from rough blankets to the smooth canvas surface. The use of asphaltic felt and asphalt-painted and sand-coated lumber in the Darrow-Hambrick machine is a further step toward the fulfillment of the smooth surface requirement by California millmen. In the case of the painted and sand-coated tables the loads are less than when employing canvas or felt, but the product is said to be cleaner and the gold extraction higher. In combination with the asphalt-felt tables their efficiency is stated to be particularly good, and their use in mills along the Mother Lode is finding much favor.

As shown in Fig. 1, the Darrow-Hambrick tables consist of a circular supporting steel frame 20 ft. in diameter, divided into 14 sections, 10 decks high, with 140 distributing boards and an equal number of plane, rectangular concentrating surfaces or trays. Only four of the latter are shown in Fig. 1, extending in front of the distributing boards. Each tray is 3 ft. by 4 ft., giving a total concentrating area of 1680 sq. ft. The surface of the trays is either painted and coated with sand, or covered with fabric or asphaltic felt. These specifications can be modified to give a table 28 ft. in diameter, divided into 21 or 24 sections 6 to 10 decks high, with total concentrating areas of 1512 to 2880 sq. ft.

The circular supporting frame is mounted on a central vertical shaft, with arms radiating to the circumference, and is revolved by a rope drive. A complete revolution is made in from 15 to 20 minutes, according to the desire of the operator. The cycle of treatment during one revolution of the table consists in (1) distributing the slime pulp to the different trays, forming a thin layer over its entire surface, (2)

gently washing the loaded trays with water to remove the light sand, and (3) discharging the concentrate into a collecting launder by means of a strong spray of water from a perforated pipe. The device thus becomes, in effect, a form of continuous and automatic canvas plant.

The free-milling character of most California gold-bearing quartz has contributed to the conservatism prevailing among the millmen of the State, as the ease with which an excellent extraction has been secured by stamp-crushing, amalgamation and concentration created a prejudice in many districts against the employment of more advanced methods. While it has been recognized for years that the tailings from many of the mills carried an appreciable gold content, many operators doubted the ability of the cyanide process or any other method to make a sufficiently large saving to justify costs attending installation and operation of necessary equipment. But the success attending the employment of the cyanide process by the North Star, Empire, Black Oak and other progressive companies has convinced even the most skeptical operators that the method will increase their earnings and many of the companies that have clung to oldtime practices for two generations are discarding their time-honored methods for the improved practice of a newer and better age.

Pitot Tubes for Gas Measurement

In view of the increasing importance of the exact measurement of the flow of gases in the chemical and metallurgical industries, an elaborate paper on this subject, by Mr. W. C. Rowse, published in the September issue of the *Journal of the American Society of Mechanical Engineers*, is of considerable interest.

The pitot tube as a means of measuring gases has the advantage of being correct in principle, inexpensive, portable, and is, in general, easily applied. But the accuracy of the different forms of pitot tubes has long been questioned, the maker of each form supposing that his tube is correct, while as a matter of fact no two forms of tube agree.

The purpose of Mr. Rowse's experiments, which were made

FIG. 1.—ARRANGEMENT OF TESTS

in the laboratories of the University of Wisconsin, was, first, to investigate the reliability of the pitot tube as a means of measuring gases, and second, to ascertain which forms of the pitot tube now in common use give correct and which incorrect results in the measurement of gases.

The method of procedure was to force air through a pipe in which the pitot tube to be tested was inserted, together with a standard gas meter. As standard, a Thomas electric gas meter (described in some detail in our Vol. IX, page 162, March, 1911) was chosen.

The apparatus used in the experiments on pitot tubes is shown diagrammatically in Fig. 1.

A No. 2½ Sirocco fan driven by a 7½-hp direct-current shunt-wound motor forced air through the Thomas meter into a galvanized iron pipe, 12 in. in diameter, in which the pitot tube to be tested was inserted.

Variable resistances were placed in series with both the field and the armature of the motor, thus making possible a wide variation in speed. A stationary tachometer belted to the fan

was so located that it could be observed at all times by the experimenter at the pitot tube. The field rheostat was brought within reach of the operator so that the fan could be maintained at any desired constant speed during a test.

Screens were inserted at the points shown in Fig. 1 in order to break up eddies and whirls and to have the air flow as nearly parallel as possible at the point where the pitot tube readings were taken. All joints between the Thomas meter and the pitot tube were made thoroughly air-tight to prevent leakage. The barrel of the Thomas meter was lagged by three thicknesses of heavy blanket in order to prevent any possibility of error due to radiation to or from the meter casing.

The experimenter was stationed directly under the pitot tube and all readings were taken at this point. A mercury barometer, hung on the adjacent wall, gave the atmospheric pressure, and a manometer inclined at a 10 to 1 slope made it possible to determine accurately the static pressure in the pipe above atmosphere. The dry-bulb thermometer indicated the temperature of the air flowing in the pipe and together with the wet-bulb thermometer gave readings from which the humidity could be determined.

The pitot tube is a well-known measuring instrument and needs only a brief description. It consists essentially of two parts, a dynamic tube pointing upstream, which converts the sum of the pressure energy and the velocity energy into a head which may be measured, and a means of determining the pressure head (or static pressure) alone. The difference between the dynamic head and the static pressure head is the velocity head h in the fundamental formula for the flow of fluids

$$v = \sqrt{2gh}$$

where

v = velocity in ft. per second,

g = 32.2 ft. per second per second,

h = mean velocity head in ft. of the fluid flowing.

It has been satisfactorily proved and accepted that the dynamic tube gives the correct pressure if the tube points parallel to the current. But it is a very difficult matter to obtain the correct static pressure on account of secondary velocity effects. Therefore the study of the accuracy of the pitot tube resolves itself into a correct study of the correct method of obtaining the static pressure at the given cross-section where the tube is inserted.

Each pitot tube tested had as a part of the tube a means of determining the static pressure, and readings of the velocity head were obtained by using this pitot-tube static pressure. Simultaneous readings of the velocity head were obtained by using a piezometer ring for the static pressure together with the dynamic tube of the pitot tube under test. This is further illustrated by reference to Fig. 1. Manometer B gives the velocity head by using the piezometer static pressure, and manometer C gives the velocity head by using the pitot-tube static pressure. In both cases the same dynamic tube pressure is used. This piezometer, even if it were possible to be in error, would always indicate the same pressure under the same conditions irrespective of the tube under test and thus it afforded an additional means of comparison independent of the Thomas meter.

The piezometer is shown in Fig. 1 and is simply an air-tight annular space about the pipe, connected with the interior of the pipe by six small holes 0.04 in. in diameter.

The velocity of a gas flowing through a pipe is much greater at the center than near the walls of the pipe. In addition, it was apparent from the tests that the gas flows through the pipe with a wave or spiral motion even when many screens are inserted to straighten out the stream lines. Therefore, it was necessary to take a large number of readings across two diameters of the pipe. The total area of the pipe was divided into five concentric annular areas and four readings of the velocity head were obtained in each test at the center of each annular area, thus giving 20 readings from which the mean velocity head could be calculated. Since the velocity varies as the square root of the velocity head it was necessary to average

the square roots of each of the 20 readings, and the square of this average represented the mean velocity head. Readings were also taken at the center of the pipe in order to determine if any definite relation existed between the mean velocity head and the velocity head at the center of the pipe.

The pitot tube under test was held in place by means of a brass bushing or holder which could be fastened by screws to brass facings soldered to the outside of the galvanized air pipe. The facings were 90 deg. apart, thus permitting readings to be taken on both the horizontal and vertical diameters.

The principal characteristics of the various pitot tubes tested are indicated in the table given in the summary at the end of this article.

The author proceeds to describe in detail the gages for measuring the velocity heads, and then gives an account of the procedure in making the experiments and calculations. The results of the tests are given in a long series of tables and diagrams.

The principal results are summed up in table 1, in which the terms M , N , Q , U , Z have the meaning explained by the following formulas:

$$C_1 = MC_2 \text{ or } M = \frac{C_1}{C_2}$$

$$C_1 = NC_3 \text{ or } N = \frac{C_1}{C_3}$$

$$C_3 = QC_2 \text{ or } Q = \frac{C_3}{C_2}$$

$$U' = \sqrt{2gh_1} = \sqrt{2gUh_3} \text{ or } U = \frac{h_1}{h_3}$$

$$U' = \sqrt{2gh_2} = \sqrt{2gZh_4} \text{ or } Z = \frac{h_1}{h_4}$$

where

C_1 = cu. ft. of air per minute by Thomas meter

C_2 = cu. ft. of air per minute by the pitot tube using the pitot static pressure

C_3 = cu. ft. of air per minute by pitot dynamic tube and the piezometer static pressure

U' and U = velocity of the air flowing in ft. per sec.

h_1 = mean velocity head in ft. of air flowing, obtained by the pitot tube using the pitot static pressure

h_3 = velocity head in ft. of air at the center of the pipe obtained in the same manner as h_1

h_2 = mean velocity head in ft. of air flowing, obtained by the pitot dynamic tube and the piezometer static pressure

h_4 = velocity head in ft. of air at the center of the pipe, obtained in the same manner as h_3

M and N are, therefore, coefficients by which the actual results obtained by the pitot tube must be multiplied to obtain the correct flow of gas. Q gives the coefficient by which the results from the pitot tube alone must be multiplied to obtain the same discharge as that shown by the pitot dynamic tube and the piezometer. U' and Z state the relations between the velocity head at the center of the pipe and the mean velocity head as determined by the two methods used in the experiments.

(The significance of the figures in table 1 will be clear from the above definitions. For instance, if we want to know what type of pitot tube used alone for getting the static pressure gives the highest accuracy, we have to look up the figures for Q which represent the coefficient by which the results from the pitot tube alone must be multiplied to obtain the same discharge as that shown by the pitot dynamic tube and the piezometer. The nearer to unity the value of Q , the more exact is the pitot tube in question. From the table we see that Q is nearest unity in case of pitot tube V , the standard tube of the American Blower Company. The value of Q in this case is 0.9992, the error, therefore, only 0.08 per cent.)

From a study of the summary, table 1, Mr. Rowse draws the following general results and conclusions:

(a) The pitot tube as a means of measuring gases is reliable within approximately 1 per cent when the static pressure is correctly obtained and when all readings are taken with a sufficient degree of refinement; in order to obtain this degree of accuracy the pitot tube should be preceded by a length of pipe 20 to 38 times the pipe diameter in order to make the flow of gas as nearly uniform across the section of the pipe as possible.

(b) All the methods of obtaining the dynamic head used in these experiments, including the German Stauscheibe (*S*), give accurate results.

(c) The most reliable and accurate means of obtaining the static pressure is the piezometer or its equivalent, the results of 138 separate tests using the piezometer static pressure agreeing with the Thomas meter within an average of 0.33 per cent;

TABLE I

	Name of Tube	<i>M</i>	<i>N</i>	<i>Q</i>	<i>U</i>	<i>Z</i>
	A	1.0614	1.0175	1.0413	0.7856	0.7936
	B			1.0576	0.8019	0.7888
	C			1.0343	0.7996	0.7880
	*C	1.0346	0.9952	1.0384	0.8107	0.8066
	D			1.0369	0.7927	0.7942
	E			1.0489	0.7885	0.7898
	X	1.0987	0.9925	1.1074	0.7656	0.7887
	G	1.0676	1.0085	0.9989	0.8100	0.8164
	H	1.0218	1.0152	1.0065	0.7968	0.7957
	Y	1.0024	1.0017	0.9992	0.8002	0.7996
	K	1.0669	0.9924	1.0626	0.7617	0.8115
	L	1.0104	1.0032	1.0064	0.7593	0.8112
	A		1.0033		0.7884	0.7986
	S	0.9861	1.0016	0.9844	0.7780	0.8228

these results show beyond any doubt that the static pressure is constant across any section of a pipe in which gas is flowing at a uniform rate.

(d) Of the methods of obtaining the static pressure by the pitot tube itself, the most reliable and accurate is by means of a very small hole in a perfectly smooth surface, as in pitot tube Y.

(e) The long slots for obtaining the static pressure are not reliable and give results which are in error from 3.5 to 10 per cent. The length of the slots or the thickness of the outer tube do not appear to affect the accuracy of the tube.

(f) The beveled tube for obtaining the static pressure as used in pitot tubes K and L is not reliable. A very slight change in the angle of bevel produces an appreciable change in the result. In taking a traverse of a pipe the sides of the pipe affect the readings. But the greatest error is produced by the uncertainty as to whether the tube is pointing directly upstream. If the tube is off 20 deg. in one direction an error of 85 per cent in the velocity head is introduced.

(g) The Stauscheibe gives accurate results using either the static reading from the Stauscheibe and a special formula or by

using the piezometer static with the usual formula for the pitot tubes. In the first case the agreement is within 1.4 per cent and in the second within 0.16 per cent.

(h) It appears that an approximate relation exists between the mean velocity head of a gas flowing through the pipe and the velocity head found by placing the tube at the center of the pipe. For a 12-in. galvanized iron pipe results within 2 per cent may be expected from using the formula

$$v = V 2g / 0.80h_c$$

where

v = velocity in feet per second

$g = 32.2$ feet per second per second

h_c = velocity head in in. of gasoline at the center of the pipe obtained in a correct manner.

Electric Furnaces, Their Design, Characteristics and Commercial Application.

By Woolsey McA. Johnson and George N. Sieger.

The Electric Furnace Structurally Considered.

Certain electric furnaces, as the carborundum furnace or the graphite furnace, are not strictly metallurgical structures, for they are simply built up and torn down after each run. This is a perfectly proper procedure, for the high temperature

FIG. 1.—SECTIONAL VIEW OF OBLONG OR SQUARE FURNACE SHOWING SIMPLE MANNER OF TIEING. OUTSIDE COURSE IS TO BE LAID IN CEMENT MORTAR UNLESS IN METAL CASE. FURNACE BUILT ON TABLE OF REINFORCED CONCRETE

(2200 C. to 2500°C.) would make any permanent furnace an engineering impossibility at present and it would not be good business with the present handsome margin of profit to bother about the unattainable.

But certain other furnaces which have a direct competition with pyro-metallurgical furnaces must be built so that the cost for repairs and renewals is within fixed industrial limits. Such a furnace must have its two basic mechanical elements—the refractory lining and the structural "iron-work" that holds lining in place,—of a design suitable for its metallurgical needs. The refractory lining must resist the action of such hot slags and metals as it is to contain. The "iron-work" (a somewhat indefinite term used to cover a multitude of virtuous devices) holds the lining and brick work together so that it is a self-contained piece of apparatus and one that will not fall apart.

Just as in any industrial concern we have older men giving advice and acting for conservatism, and young men full of energy and tireless refractoriness, so in a metallurgical furnace we have the complementary parts of firebrick and steel each doing a different duty.

From an idealistic standpoint firebrick work is supposed to possess no mechanical strength, except resistance to crushing.

We must then consider that the bricks are bound together by the inwardly-directed force of compression, which comes originally from the tension rods of the outside framework and that structural coherence comes from friction. Practically it is possible to depart from theory, for the strength given by the mortar is sometimes great.

When it comes down to a question of facts, the design and erection of a furnace is largely a matter of practical exper-

FIG. 2.—SECTION OF FURNACE BUILT OF CAST IRON PLATES ALSO ON TABLE OF A REINFORCED CONCRETE

ience and "get-there-ness." But if interpreted with engineering common-sense, theoretical considerations are of value. Indeed they are always present unconsciously in the mind of many so-called ignorant workmen and it is the wise engineer who avails himself of truth and knowledge from any source.

Undoubtedly the simplest form of "iron-work" for a furnace is a box made of sheet steel $\frac{1}{8}$ in. to $\frac{3}{8}$ in. thick, reinforced on the corners with riveted angle bars. See Fig. 1. This furnace can be securely tied by tie rods made in identical manner to tie rods on a square brick chimney. This form is a good one for an experimental furnace. The brick work is laid inside in dimensions of multiples of $4\frac{1}{2}$ inch.

Cast-iron plates with flanges running both horizontally and

FIG. 3.—SECTIONAL VIEW OF SIMPLE "POT" FURNACE BUILT OF "RADIUS" BRICK OR OF "KEY" BRICK. OUTSIDE COURSE MUST BE LAID IN CEMENT MORTAR UNLESS STEEL SHELL IS USED

vertically makes a better job of this design often, especially if the furnace is a permanent one. See Fig. 2. This specially cast stuff costs more than sheet steel.

Cast steel plates are practically perfect, but their cost is the highest.

Electrodes are inserted in holes. Such furnaces are built of insulated bolted sections.

Cooling of the outside by water is the way when any severe duty is placed on the refractory lining. These water-jackets, spray-plates, or bosh-plates have to be held in place in a majority of cases by the inwardly-acting force of steel rods or steel hoops.

Where a round furnace is used the steel shell is made in the form of a hollow cylinder. Steel hoops with adjustable means of loosening or tightening can be used when great mechanical strength is demanded. See Fig. 3.

An oblong furnace is tied with rows of rods running in all three directions and engaging buck-stays. See Fig. 4. Buck-stays are made of cast iron, I-beams or old rails. A buck-stay is a mechanically strong piece of metal backing up the brick work and taking the outward thrust of expansion.

Brick walls laid in cement mortar or reinforced concrete walls can be used for the outer walls, provided the metallurgical duty is not severe. This makes the outer wall one-piece.

In any case we must conceive of the lining holding the contents, the outer walls holding the lining and the "iron-work"

FIG. 4.—FURNACE WITH CAST-IRON BUCKSTAYS AND TIE-RODS RUNNING AT RIGHT ANGLES TO TAKE THRUST OF ARCH

holding the outer walls. These things must be grasped by the mind at the same time. The relative duty and the association of different functions of the parts operate in good design for a common end. For instance, the ultimate force is the tension on the tie rods, coming from the turning of the nuts or twisting the turn-buckles. Opposed to this is the expansion of the firebrick on heating. These forces must be in equilibrium. Otherwise distortion or possibly rupture ensues.

Proper allowance for this fact must be made in design and the furnace must be watched on heating up and tie rods slackened. Probably the simplest way to compensate such forces is by the use of spiral steel compression springs acting on ends or in middle of tension rods. In such a manner the force is progressively compensated and without trouble and without care on the part of furnace-man and engineer. Were it not for increased expense, the authors would never design any furnace without use of spiral compression springs. Accordingly, where question of expansion is serious, springs on rods can be used. Fig. 5 shows one manner of using compression springs.

Tie rods are usually made by welding bightened "bolt-ends" to steel stock, but the threads can be cut if convenient. Turn-buckles and clevis nuts can be used but do not seem to be as serviceable for all 'round work as nuts and bolts. In welding a bolt-end to a tie-rod allowance must be made for the fact that the cut of thread has diminished the effective area of bolt-end

by just so much as twice the distance from the outer circumference to the root of thread. To use square $\frac{1}{2}$ -in. rods to a $\frac{3}{4}$ -in. bolt-end, square $\frac{3}{4}$ -in. rods to 1-in. bolt-ends, and so forth, is a practical rule. In spite of proper personal pride of the blacksmith, the weld has only the strength of from 40% to 80% of original stock. The weld should be a "scarf weld" near the bolt-end made so as to thicken up the stock as much as possible.

The preceding description can be summed up as follows:

(1) There should be a lining that is refractory and this lining must be held in place by compression.

(2) There should be a shell or outer wall that distributes this compressive force uniformly to the lining.

(3) The "iron-work" should receive this inwardly acting force from the strain of tension of steel.

(4) All of the above must be so proportioned that each does its proper work.

When the above is achieved, the furnace is perfect.

Electro-Metallurgical Idiosyncrasies

In general, an electric furnace for conditions below 1600°C. resembles in its construction ordinary pyro-metallurgical fur-

FIG. 5.—ELECTRIC FURNACE CONSTRUCTION SHOWING USE OF COMPRESSION SPRINGS

naces. There are three differences, however, one electro-metallurgical, one electrical and one magnetic in cause.

If at any time the furnace does not functionize, or if too much electrical energy is applied, the temperature of the contents will rise in short period to an extraordinary degree, before the radiation or smelting will cool it down. This is liable to happen at any time. Accordingly the lining must be able to stand self-abuse and extraordinary hard work.

So also with electric current; the tie rods and steel are conductors and if accidentally in contact with both sides of power line, a bad short circuit ensues. By inserting in convenient places $\frac{1}{4}$ in. strips of John B. Pratt Co.'s "Vulca-beston" with bearing plates of $\frac{1}{4}$ in. bar iron this cannot happen. This is a wise precaution although the firebrick alone is generally enough of an insulator.

Most electric furnaces employ alternating current. The "iron-work" therefore, must be broken where possible by air gaps, by brick or by "Vulca-beston," with structural strength still preserved. This point can be seen in the design shown in Fig. 5. Otherwise, the inductive drop due to voltage absorbed for no other purpose but to magnetize the "iron work" with each alteration becomes commercially important and power factor especially in large units drops to low figure.

Refractories

The subject of refractories is a large one and also a peculiar one. The backward state of this art can be well seen by the

fact that the same substance, aluminum silicate, is used for firebrick to keep in heat and as a heat insulator, and for retorts, muffles, and crucibles to bring in heat, which should be heat conductors. (Cf W. McA. Johnson, *Electro-chem. & Met. Industry*, Vol. III, page 214 and Vol. IV, page 6.)

But at present the great amount of work which is being done in metallurgical and chemical engineering circles on the subject of refractories is sure to bring eventually discoveries of great commercial worth. If some practical scientist should invent and perfect a refractory, inert to usual metallurgical substances as slags at a temperature up to 1700° C. and a fair non-conductor of heat and electricity at that temperature, he would be performing an invaluable service to the profession. Furthermore, he might make a fortune.

The general kind of refractory is made of silicate of alumina and goes by the name of common firebrick. This is manufactured of two physically different forms of material. (1) plastic or hot clay and (2) "grog," i.e., coarse particles of crushed burnt fireclay. The former material gives firebrick strength, the latter gives them cohesive powers.

Firebrick vary in refractoriness depending on impurities in clay on manufacture and physical distribution of impurities. In general, it can be said that any substance that tends to make a blast furnace slag more liquid, as soda, iron oxide, or lime, diminishes the refractoriness of firebrick. Good firebrick will stand a heat of 1475°C. to 1525°C., while "rebrick" are made that will stand 1600°C.

Firebrick at any temperature will not long stand hot liquid slag, especially in an electric furnace, unless they are cooled in some manner. In the latter case they simply are eaten away until the cooling is such that a protective layer of congealed slag stops further corrosion.

Firebrick are made in many shapes and sizes. Ordinary stock shapes are as follows:

Straight	9" x 4 $\frac{1}{2}$ " x 2 $\frac{1}{2}$ "
Soap	9" x 2 $\frac{1}{2}$ " x 2 $\frac{1}{2}$ "
No. 1 Split	9" x 4 $\frac{1}{2}$ " x 1 $\frac{1}{4}$ "
No. 2 "	9" x 4 $\frac{1}{2}$ " x 2"
Large Straight	9" x 6 $\frac{3}{4}$ " x 2 $\frac{1}{2}$ "
Plate	12" x 12" x 2"
Slab	23" x 5" x 3"
Slab	28" x 8" x 5"
No. 1 Arch	9" x 4 $\frac{1}{2}$ " x 2 $\frac{1}{2}$ " to 2 $\frac{1}{8}$ "
No. 2 "	9" x 4 $\frac{1}{2}$ " x 2 $\frac{1}{2}$ " " 1 $\frac{3}{8}$ "
No. 3 "	9" x 4 $\frac{1}{2}$ " x 2 $\frac{1}{2}$ " " 1 $\frac{1}{8}$ "
"Bung" "	9" x 4 $\frac{1}{2}$ " x 2 $\frac{1}{2}$ " " 2 $\frac{3}{8}$ "
No. 1 Key	9" x 4 $\frac{1}{2}$ " to 4" x 2 $\frac{1}{2}$ "
No. 2 "	9" x 4 $\frac{1}{2}$ " to 3 $\frac{1}{2}$ " x 2 $\frac{1}{2}$ "
No. 3 "	9" x 4 $\frac{1}{2}$ " to 3" x 2 $\frac{1}{2}$ "
No. 4 "	9" x 4 $\frac{1}{2}$ " to 2 $\frac{1}{4}$ " x 2 $\frac{1}{2}$ "
No. 1 Wedge	9" x 4 $\frac{1}{2}$ " x 2 $\frac{1}{2}$ " to 1 $\frac{1}{8}$ "
No. 2 "	9" x 4 $\frac{1}{2}$ " x 2 $\frac{1}{2}$ " to 1 $\frac{1}{2}$ "
No. 3 "	9" x 4 $\frac{1}{2}$ " x 3" to 2"

Radius brick 9" x 6 $\frac{3}{4}$ " x 4 $\frac{1}{2}$ " to 2 $\frac{1}{2}$ " are especially convenient at times as well as big blocks 18" x 12" x 8", and "skew backs." Tiles, slabs and plates are made in a variety of other sizes.

With an intelligent mason, furnished with plenty of sharp "skutches" and chisels, almost any furnace can be built of above shapes. Not unoccasionally, however, it is business to have made special shapes, as for instance for a "flat" arch, or for ring around charging hole. But by use of beveled edges and by applying plenty of compressive force many things can be done, if ingenuity and persistence are at hand.

There are three other kinds of refractories that are much more expensive than firebrick, but better for use where high heats are used and special conditions are to be met. These are magnesite brick, chrome brick and silica brick, made respectively of basic, neutral, and acid material. All these brick have high coefficients of expansion on heating and expansion must be liberally allowed for. See Fig. 6.

Magnesite brick are used with a basic slag, for instance, in

modern copper converting or in basic open hearth bottoms. They can be laid in fine dust, milled from old brick mixed with hot tar, linseed oil or water-glass. They are also laid dry. A bottom can be made of old magnesite brick, dust, and water-glass, just as concrete is laid, and if dried slowly

FIG. 6.—TEST OF EXPANSION OF REFRACTORIES

and thoroughly baked it will hold metal fairly well. The water-glass, of course, diminishes the refractoriness of the work, but adds to other properties, such as coherence.

Chrome brick are used at times as an equivalent of magnesite brick. They make an inert insert between courses of magnesite brick and silica brick which might flux together, and also are suitable around tap hole of furnace. Both chrome and magnesite brick conduct heat several (2 to 4) times as well as ordinary firebrick.

Silica brick are laid for arches which are subjected to considerable heat, e.g., in Heroult electric steel refining furnace. Silica brick are made out of special silicious material, e.g., ground sandstone mixed with a little lime "putty" as a bond, and then burned. They are laid in mortar of same material out of which it is made. All three kinds are only made in few stock sizes. They are all apt to be warped to some extent in burning, and are not true to shape or size at all. All these as well as common firebrick are porous to a considerable degree.

Other kinds of brick can be used but are less common, e.g., "bauxite" and "alundum" brick, in special cases to meet special conditions. Of course, in an electric furnace, with its reducing atmosphere and in an electric furnace plant where there are always plenty of stub ends of electrodes, carbon brick are fine. But sooner or later they burn out by accidental or incidental oxidation. They are all right for experimental work or where it is commercial to run a furnace a short time and then rebuild it. They can be laid up in a mixture of tar and carbon dust.

It is well to have several barrels of pugged firebrick mixture bought from a firebrick manufacturer on hand in any small plant. This can be rammed into the interstices when necessary,—such as when changing from "headers" to "rowlock" or

FIG. 7.—SIMPLE ARCH SHOWING "RISE," "SPAN" AND "SKEWBACKS"

"stretchers" the courses do not work even. "Asbestos-retort" cement makes a good filling where not exposed to temperature above 1200 deg. C. Johns Manville or American seal are good brands.

Electrically sintered magnesite with a special bond, which is furnished the trade by the Norton Co. is of value in special places in furnaces with basic lining. It should be tamped in warm with red hot steel tampers.

All brick work should be laid tight, brick to brick, with expansion joints where needed and where designed. Where the firebrick are subjected to severe duty, they should be dipped in thin "fire-clay soup" and tapped with a mason's hammer into place. *The mortar should be same stuff as brick*, very fine and mixed thin with water or other liquid. In certain cases, the brick can be laid with thicker mortar and by use of a trowel. Not unseldom a little cement can be mixed with fire

FIG. 8.—SHOWING ARCH AND MANNER OF BREAKING JOINTS IN AN ARCH. ALSO THE BACKING OF THE "SKEWS" WITH T-BARS HELD IN PLACE BY BUCKSTAYS

clay, especially where brickwork is exposed to weather or where mechanical strength is needed. But this is a matter of judgment, for cement diminishes refractoriness.

But, when all things are considered, the use of firebrick and other refractories so as to produce results cheaply and efficiently is an art, not a science,—an art of understanding conditions and ways of making things practical, not a science or an academic theory.

Laying an Arch

The laying of an arch is a matter that requires care and conscience. The first thing to do is to figure out the "sweep." The "sweep" is rise in inches per running horizontal foot of arch. This changes in a circular arch but as most metallurgical arches are built with practically constant curvature, the term sweep can be used all right. The "span" is distance between lower points of "skew-backs." The "rise" or "raise" is distance from bottom of "key-brick" to line running from lowest point of skew-back. See Fig. 7.

The "sweep" of an arch has ordinarily a minimum safe value of $1\frac{1}{2}$ " to $1\frac{1}{2}$ ". But the work must be carefully done and on intermittent service of furnace an arch with sweep of $1\frac{1}{2}$ " to foot or $4\frac{1}{2}$ " "rise" to $7\frac{1}{2}$ " "span" would not stand unless made of key or wedge brick, and unless the "skew-backs" were securely tied in. A sweep of 2" to one foot is a good figure to keep in one's head.

Arches, as everyone knows, are laid on wooden forms, which are burned out on drying furnace. The important part of an arch is the "skew-back." See Fig. 8. These should be of large blocks and slightly bigger on skew-face than thickness of arch. The skew face is flat to receive the first brick in perfect contact. *Skewbacks must be backed up on rear with first-class brickwork.* The final backing is an angle bar or a tee bar set in the brickwork and this should be held in place perfectly by the "iron work." It is the first rule of arch construction to "look after your 'skew-backs,'" and to see that they cannot be displaced any fraction of an inch.

Every surface of bricks in an arch must be in good mechanical fit with surface touching, since there can be no sliding along planes of contact. For many places where "span" is short, big blocks can be used to replace the arch. For a short span a single block supported at both ends on walls, suffices. By holding these down securely it is possible to span with two of these set "cantilever" fashion a full 30". See Fig. 9. In other places these can be cut in form of "jack arch" or "Dutch arch," to use another colloquial term.

An arch is necessarily laid tight and with "joints broken" as in all brickwork and with a smooth fit on all surfaces. See Fig. 10. The final key-bricks are driven home with a hammer. The blow should be received on a wood, such as a short end

of a 2" x 4" and never on the brick directly. Arches are laid with especial care when they have heat on both sides of them.

It can be remarked that any big block such as one for a "skew-back" or a "Dutch arch," had best be cut on a bed of sand. The bed of sand absorbs the jar of the cutting tools and stops the generation of fissures and possible ultimate cracking of the block.

As brick are laid wet, the furnace must be dried out. This drying should be slow with a gradual raise of the heat. Twenty-four hours drying for each $4\frac{1}{2}$ " or for each course of brick is a safe rule. Thus a furnace with 9" wall would take 48 hours to dry, and with an 18" wall, 96 hours. As the brick

FIG. 9.—SHOWING WAY OF COVERING OVER A FLUE ON A SMALL FURNACE WITHOUT USE OF AN ARCH. THIS IS PRACTICAL TO SPANS AS LARGE AS 30" TO 36". THIS FORM OF CONSTRUCTION IS PARTICULARLY APPLICABLE WHERE A FLAT COVERING IS ADVANTAGEOUS

retain moisture and are decidedly hygroscopic a great heat applied suddenly would generate steam so fast as to cause trouble and a wood fire is used, particularly at first. Afterward a coke fire or an electrically heated coke resistance can be employed, but this is a little risky.

At the time the furnace is being heated up the tie rods should be adjusted, so as to meet properly the increasing strain.* Care is taken in bringing a furnace up to working temperature and a policy of conservatism is the only one to be employed. The injunction to "play it safe" is about as good advice as can be given.

Water Cooling

We have learned in the case of slag tap-holes, electrode ports, and electrode connectors, that the way to reduce the cost of repairs and renewals to a minimum was to use where we could, water-cooled metal instead of a refractory. For as long as the water was circulated freely the metal could not be destroyed and a permanent piece of apparatus was made.

Now although electric heat is expensive and heat insulation is desirable, provided it is attainable, it is not good business to try to save money in the power item and waste twice as much money in the repair and renewals item. For many purposes water-cooling of an electric furnace in a manner similar to that used where locomotive fire-box, and iron, copper or lead blast-furnace is water-cooled is a proper design.

A characteristic of electric furnaces is in many types an excessive local heating in places and at times. This produces bad results and if the electric furnace is to have any extended commercial application beyond its present restricted limits, troubles arising from the afore-mentioned causes must be eliminated or held under control.

There is, all things considered, no better way or at least no simpler way to attain permanency of furnace shape than by water-cooling. While we have in this connection the primal disadvantage of electrothermanism as against its competitors of high-cost of the heat unit, still we have at disposal the great primal advantage of convenience of use and application of

electrically generated heat, when this use and this application is understood. This will be seen in the following reasoning.

The thermal efficiency of electric furnaces is always high because of direct application of energy without use of considerable matter. In carbon-heated furnaces the waste gases are a source of loss of thermal energy even when recuperators and regenerators are employed. In electric furnaces, the heating agent is the ether, or to use the common-sense term of wise old Benjamin Franklin, the "electric fluid." This generates heat directly in an imponderable form and leaves all its energy in an easily available commercial form. Moreover the rate of smelting by electrical means can be made high. 11 ratio of calories (or B. T. U.s) to cubic foot of working space per hour is higher other things being equal, the proportion of heat lost in radiation, conduction, etc., is reduced. Consequently, the thermal efficiency is higher as "smelting rate" is increased and water-cooling entails only a small percentage of heat loss. Briefly expressed, a lot of work is done in a little space.

Just here is where the electric furnace has an unsuspected thermal advantage over its competitors, for the "smelting rate" can be increased to higher values than in case of "carbon-heated" furnaces. For instance, experimental furnaces of the Continuous Zinc Furnace Company have been operated 300 lbs. of ore charged per cubic foot of laboratory space per day whereas zinc furnaces fired by gas operate in certain cases at 5 lb. of ore charged per cubic foot of laboratory space per 24 hours. Such a state of affairs puts a new light on the competition of electricity and carbon for heating furnaces. And we find that water-cooling does not possess great terrors for the designs of electric furnaces, if at the time the true principles are understood, but rather that water-cooling instills a wise and moderate respect and liking for the great service it can effect in the way of reducing cost of repairs, and increasing length of campaign.

A peculiar fact is disclosed by a study of water-cooling. The thermal conductivity of all substances increases greatly with rise of temperature. Accordingly if we have an outside

FIG. 10.—SHOWING MANNER OF LAYING A "DUTCH ARCH" SHAPED AND CHEAP FOR SPANS UP TO 30" TO 40" OR EVEN LARGER. THIS FORM OF CONSTRUCTION IS PARTICULARLY A GOOD WHERE FLAT COVER OF SOME SIZE IS DESIRED

temperature of 250 deg. C. in one case and outside temperature of 60 deg. C. in the case of water-cooled, we have a much less resistance to flow of heat in the second case. So, a thin water-cooled shell can equal as a heat-insulator a thick brick wall. It can be conceived that the "flow of water frees the walls of the furnace and so keeps heat inside."

Water-cooling can be applied to electric furnaces in any of the ways known in ordinary metallurgical practice.

These are as follows:

- (1) Cast-iron water jackets.
- (2) Pressed steel water-jackets with joints and stay-bolts welded by oxy-acetylene flame.

*Peters.

(3) Internal bronze-cooling plates same as used in back of iron-blast furnace, where a thick structural stony wall is desired.

(4) Spray-plates such as used on iron-blast furnaces. These are cheap and simple. The spray should be under a head not to exceed 10 feet and the plates should be smooth. Spray-plates are "sloppy" even when well designed, but they are the most efficient and most practical of all devices in all other respects.

In the three first-mentioned cases, care should be paid to see that no steam pockets are formed or that no sediment is deposited. By having *water enter at bottom and come out at top* and by having baffle plates to secure good circulation these troubles are obviated. In all cases the cooling metal surface is held mechanically firm to lining.

In considering case of water-cooling versus refractory walls it is well to hold in mind the nature of work to be done. If a slow "soaking" heat is the kind that work requires, design your furnace with no water-cooling. If a rapid transfer of heat is required, design your furnace with adequate cooling devices.

Or if one part of the furnace needs a "soaking" heat and the other a "rushing" heat, combine two forms of design in a composite manner.

The difference in extreme cases is deep-seated and a rational regard for this fundamental is an essential in making a good design of a commercial electric furnace.

Heat Insulation of Furnaces

We have just seen that such furnaces as are operated with a slow transfer of heat from its source to the point of absorption or of the "soaking-heat type" are not suited for water-cooling. These furnaces are usually resistance furnaces of the Cowles type. For instance, in the several forms of annealing furnaces now on the market it would be unwise to attempt to water-cool, especially as they are built in small sizes and thermal efficiency is diminished by such a procedure. In the case of small units water-cooling proves to be an undesirable complication.

In these cases the resistors are some form of carbon or of inert metal wire. The sides can be of some form of carbon with less electrical conductivity as charcoal. This forms an effective heat insulator and one resistant to fusion. But of course, if any air should touch it, total oxidation would quickly follow. Carborundum or silicon are other infusible substances that are used for wall next to resistor.

The study of the heat gradient will allow a use of several refractories with different properties as the heat diminishes in intensity. Magnesite brick can be used up to a temperature of 1700° C. or a pure electrically sintered magnesite, such as is made by the Norton Co., up to 2000° C. Likewise, brick made of carborundum base such as were lately put on the market by the Carborundum Co., and "alundum" brick as offered by the Norton Co., have special uses. Carbon brick are perfect as long as oxygen with any free energy is absent. Aluminum Nitride also has possibilities for refractory linings.

All these special and novel forms of refractories have their uses but can only be used where practical trial shows them to meet the needs. Some of them are too expensive for ordinary purposes. But where duty is hard, expensive brick makes for cheaper final result. It is merely a platitude to say that the choice of brick is a balancing of first cost against cost of repairs in each individual case.

For the outer layer fire-brick, red-brick, or reinforced concrete will suffice. In building a furnace of the "soaking heat" type, effective heat insulation can be gained by the use of air spaces between different courses of brick, or by separating the courses as "stretcher" courses with no "header" courses.

Mineral wool or "kiesel guhr" on the outside either plastered on or packed in a shell of asbestos board or sheet steel will keep in the heat as long as the temperature is below 700° C. Asbestos or magnesite packing such as is furnished by the Johns-Manville Co. is another convenient form.

All these varied forms of refractories have varied uses and

applications depending on the nature of the work and on the special scientific, practical, and commercial conditions that are to be fulfilled. The commercial conditions are the weighty ones, for no matter how scientifically perfect an electric furnace is and no matter how well the engineering and practical part is, unless an electric furnace is a commercial success, it is a miscarriage. Applied science is a business and the engineer must understand the principles of business and economics to a greater extent than was once thought requisite.*

Specific Volume and Constitution of Alloys

A paper on this subject was presented by Dr. W. M. Guertler at the recent meeting of the (British) Institute of Metals in Ghent, Belgium.

Dr. Guertler's paper is of a theoretical character and follows up a previous communication of his to the Institute of Metals in which he discussed the connection between the electric conductivity of alloys and their constitution.

Diagrams are given to demonstrate the dependence of the volume of alloys on concentration and temperature and explanations are given of the influence of mechanical treatment on the volume. The latter effect is generally two-fold where a normal alloy is hammered or rolled, (1) small hollows, pores, etc., closing up and the process ceasing when all these hollows have closed up; (2) where the individual crystal grains of the aggregate are broken up the grain becomes finer and this breaking up never ceases as long as mechanical work continues. The co-operation of these two factors causes the specific volume first to decrease, then to attain a minimum and again to increase as soon as the first factor is removed by the closing up of all the cavities. This explains Wertheim's discovery that the volume of metals and alloys can be increased by intense mechanical treatment. Figures are given to show the combination or the process of crystallization with that of transformation. These figures also represent and give a general idea of the "volume" surfaces of alloys.

Arsenical Copper

In a recent paper before the (British) Institute of Metals Mr. F. Johnson discussed a method of improving the quality of arsenical copper.

In this paper the author records the results of an investigation of the properties of specially alloyed arsenical copper with a view to proving its suitability for use as locomotive stay-rods, wire for rivet manufacture and any material required to have specially high malleability, ductility and toughness combined with tensile strength and resistance to reducing-gases at high temperatures.

An improvement in quality in these respects has been obtained by adding silicon and iron to the copper in various small proportions. When added to the copper in the form of a copper-silicon-iron alloy (of low melting-point) complete deoxidation is effected and, in addition, degasification is so thorough that perfectly sound ingots are obtained. In the absence of bismuth and other like impurities, which cause red-shortness in deoxidized copper, the ingots behave perfectly when rolled at a bright-red heat, even if silicon and iron are present together in considerable excess of the amount required for deoxidation.

It is shown that silicon is a more efficient deoxidizer than iron, but that iron has a greater strengthening effect than silicon.

Complete analyses of the rolled bars have been made and it is noteworthy that the added elements confer greater toughness than is possessed by "tough-pitch" copper containing oxygen and a similar quantity of arsenic. Heat-treatment of the experimental bars in a reducing atmosphere also proves their immense superiority over "tough-pitch" arsenical and non-arsenical bars.

The experiments have been backed up by works' tests on a larger scale.

* In the article of this serial, published in the October issue, the heading of the table on the bottom of page 563 should read: Safe carrying capacity in amperes (instead of amperes per square inch).

Tensile tests at the temperature of high-pressure steam show that the specially alloyed bars are in no way inferior to "tough-pitch" copper of similar arsenic contents.

The above-mentioned improvements have not been gained at the expense of any of the properties considered to be essential in commercial "tough" copper for locomotive stay-rods.

Certain physical characteristics of the experimental bars are revealed and differences in behavior explained by the aid of the microscope.

Notes on Chemistry and Metallurgy in Great Britain

(By our Special Correspondent.)

The British Association

The presidential address of Sir Oliver Lodge (published in full in the October issue of this journal), was generally very favorably received by the daily press, but among scientific men the tone of that section of his address which dealt with "continuity" in relation to "life after death" is by no means so generally approved. There are many men with more than thirty years of "accumulated experience" of so-called psychological matters who are still without any evidence, positive or negative, on the matter.

It was a pity that Sir Oliver did not give some indication of the nature of the evidence furnished by his experience, because at present there is really nothing in the shape of evidence one way or the other. We have only the disreputable tricks of spiritualistic mediums, which would not delude an average child of ten; and scientific men are not inclined to regard such impostures as evidence or even to notice them at all. In really scientific circles the number of men is steadily increasing who are content, like Huxley, "to follow Socrates in the belief that 'the knowledge of what we do not know is perhaps the surest; and to hold that those who do not attain that knowledge, who 'presume beyond human limitations, are rightly visited with 'the punishment of becoming the slaves of their own delusions, 'the worshippers of idols, which are their own works as much 'as if they were hand made.'" [Huxley, Nineteenth Century, "March, 1895.]

The true essence of the whole matter is to be found in the preface to the Pious Editor's Creed in James Russell Lowell's "Biglow Papers," and although discussion may be just as much out of place in these columns as it is in the meeting, to the British Association, the following brief extract from that preface may perhaps be of service in preventing anyone with psychological tendencies from searching too deeply after the unknowable:

"But the clergyman chooses to walk off to the extreme 'edge of the world, and to throw such seed as he has clear 'over into that darkness which he calls the next life. As if 'next did not mean nearest; and as if any life were nearer 'than that immediately present one which boils and eddies all 'round him at the caucus, the ratification meeting, and the 'polls! Who taught him to exhort men to prepare for eternity 'as for some future era of which the present forms no integral 'part? The arrow which Time is now turning runs through 'the everlasting, and in that must he plant or nowhere. Yet 'he would fain believe and teach that we are going to have 'more of eternity than we have now. This going of his is 'like that of the auctioneer on which gone follows before we 'have made up our minds to bid."

Transmutation of Metals

Mr. Frederick Soddy in his discourse on "Radio Active Elements and the Periodic Law," explained how it was now possible in consequence of recent discoveries to assign their proper places in the periodic table of the elements to the disintegration series of radio-active materials such as uranium, thorium and actinium.

He said that the chemical analysis of matter had hitherto appeared to be ultimate, because it had been impossible to dis-

tinguish between elements which were apparently chemically identical and not separable unless they were in process of change one into the other. But for those elements of which the evolution was still going on the places in the periodic table were found to be occupied on the average by no less than four, the atomic weights of which varied as much as eight units.

The same conditions were probably true for the rest of the table, and every known element might be composed of a group of non-separable elements, apparently occupying the same place, and the atomic weights would not be a real constant, but a mean value.

These advances showed that matter was much more complex than had hitherto been revealed by chemical analysis, and at the same time indicated that atomic constitution might be more simple than had been supposed from the lack of simple numerical relations between the atomic weights. These group-elements all gave the same spectra owing to similarity in their electronic system.

Madame Curie possessed about a gram of radium, and intended to compare the spectra of radium-lead and ordinary lead. He thought they would be exactly the same; but Madame Curie did not agree. He did not see any reasons why, under suitable conditions, it should not be possible to change thallium or mercury into gold. It only needed the expulsion of one alpha particle from thorium, which could be effected at a potential of 1,000,000 volts; but at present it was difficult to work with over 100,000 volts. Also, the expulsion of one beta particle and two alpha particles from lead ought to form gold, and the intermediate product would be bismuth.

Radio-Elements

Mr. Alexander Fleck, in the course of an interesting paper, said that since last year's meeting the study of the chemistry of the radio-elements had been continued, and the chemical nature of eleven additional radio-elements had been experimentally ascertained. It appeared that Uranium X and radio-actinium were chemically identical with thorium; meso-thorium —2 was chemically identical with actinium; radium-A was chemically identical with polonium; radium-C, thorium-C, actinium-C, and radium-E were chemically identical with bismuth; radium-B, thorium-B, and actinium-B were chemically identical with lead; and finally thorium-D and actinium-D were chemically identical with thallium.

The Effect of Exposure to the Atmosphere on Metallic Wires

Mr. Ernest Wilson presented a report on the results of tests designed to show the effect of exposure to London atmosphere on the electrical resistances of various metallic wires having a diameter of 0.126 in. and a length of 70 ft. These tests are a continuation of Mr. Wilson's earlier experiments of the same nature, the results of which have been communicated to the Association for some time past. The figures now given show the percentage increase in electrical resistance, at 15 deg. C., on the value found in 1911, and are for two years' exposure. 11gh conductivity copper showed an increase of 2.0 per cent; commercial aluminium, 4.4 per cent; and "Duralumin", 8.2 per cent. In the last named metal exposure has apparently induced some increase in brittleness.

Wrought Iron for Rolling Stock

The Engineering Standards Committee has issued a new specification embodying considerable alteration from the specification of August 1910. Among the more important changes are:

(1) A reduction in the number of tensile tests for best Yorkshire bar iron; (2) A similar reduction in the number of bend tests; and (3) the deletion of the quenching test; (4) the inclusion under grade "B" of the tests for plates which were included under grade "C", but with a slightly increased minimum elongation per cent, and somewhat more severe bend tests, and the insertion under grade "C" of plates of Cleveland iron quality; (5) an increase in the minimum contraction of area per cent. of original area for grade "A"

round and square bars up to $1\frac{1}{2}$ in. in diameter or section; (6) an increase in the minimum contraction of area per cent. of original area for grade "B" round and square bars up to $1\frac{1}{4}$ in. in diameter or section; (7) the optional use of standard test pieces B or F for the angles and flat bars up to 1 in. in thickness; (8) the provision of bend test pieces for blooms and billets, for bars over $2\frac{1}{2}$ in. in diameter or section, and for flats over 1 in. thick; (9) provisions for testing other blooms and billets; (10) the deflection from the tables of tensile tests of the requirements for round or square bars above 4 in. in diameter or section; and (11) the addition of a quenching test for grade "B".

The Anti-Corrosive Properties of Coal Tar

Experiments conducted by the Military Engineering Department at Brest show that the value of dry tar as a preservative of ironwork from corrosion is greatly increased by the addition of quick-lime which has the effect of rendering the coating more durable, especially in the neighborhood of sea-water. Two parts of coal tar were heated to boiling in a cast iron pan and were then triturated with one part of lime. At a temperature of about 50 deg. C., the mixture can be applied by a brush in a thin, uniform coating after the iron has previously received a coat of red lead, and drying is complete in about two days. A metal door so treated showed no sign of corrosion after 12 months, whereas ordinary paint did not withstand the action of the brackish atmosphere for more than six months. The total cost of red lead, tar compound and labor amounts to about 8d. per square yard.

Coal-Dust Explosions

The recently-published fourth report of the Explosions in Mines Committee gives the very interesting results of the experiments carried out by Dr. Wheeler in the Altofts gallery for the Mining Association of Great Britain.

The combustion of a mixture of coal-dust and air appears to proceed in two distinct stages; first, inflammation, and next explosive combustion; and in the earlier stage flame is propagated to a great extent by the combustion of gases resulting from the ignition of the dust, while in the explosive combustion stage the dust particles are entirely consumed—fixed carbon as well as volatile matter—without notable preceding liberation of gas. The times of travel and pressures at various distances recorded in experiments in which ignition was effected 500 feet from the open end of the unobstructed gallery pointed to the conclusion that combustion remained of the "inflammation" order for about 425 feet and then suddenly assumed the explosive character.

The violence of the explosive effect of a mixture of air and coal dust was found to be just as great with dust containing 16 per cent. of volatile matter as with dust giving 35 per cent. of volatile matter, and the effect produced with wood charcoal was fully as great as with coal dust. When the gallery was free from any obstruction the pressure produced at a distance of 450 feet from the point of ignition was only 16 lb. per sq. in., but when timbers, to represent roof-props in a mine, were introduced a pressure of 50 lb. per sq. in. was registered at a distance of only 225 feet.

Other experiments in which constrictions formed by 6-in. flanged angle iron, reduced the diameter of the gallery from 7 ft. 6 in. to 6 ft. 6 in. showed conclusively that the maximum pressure developed increased very largely, and, under certain conditions, was attained at much less distance from the point of ignition, while the time in which it was reached was very much reduced.

With three constrictions at 300, 350 and 400 feet from the point of ignition a maximum pressure of 152 lb. per sq. in. was developed at a distance of 450 feet as against 16 lb. per sq. in. in the clear tube. Three constrictions placed at 200, 250 and 300 feet from the ignition point resulted in a maximum pressure of 57 lb. per sq. in. at a distance of 250 feet in 66 hundredths of a second as against a pressure of 10.5 lb. at 450 feet in 1.03 second with one constriction at 200 feet.

The Co-Ordination of Engineering Research

At the summer conference of the Institution of Mechanical Engineers Mr. G. H. ROBERTS presented notes on engineering research and its co-ordination. He said that whilst engineering had reached a high stage of development as an applied science, it was remarkable that no definite system existed for communicating to the profession as a whole the results of numerous private researches which are carried on. He referred more particularly to that class of work which had a direct object in view and did not extend to side issues, and which in this country alone must be very extensive. Typical examples were furnished by the reports of the American Board of Ordnance; and there had also recently been an increasing tendency on the part of the engineering departments of our largest railway companies to interchange information.

The President, Sir H. F. Donaldson, in his presidential address delivered in April, had advocated the establishment of an engineering research committee on the lines of the Engineering Standards Committee, and the President of the Institution of Water Engineers had last June expressed the opinion that the results of very much experimental work were lost because they were not properly recorded; and when satisfactory records were kept the investigator retained his results. Railway companies and government establishments were probably least affected by considerations of competition, yet even in their cases certain investigations must be of a confidential nature.

At Woolwich Arsenal there were the ordnance factories and the inspecting and stores department of the army and navy; and the ordnance factories comprised three separate manufacturing establishments for the production of warlike stores. Each was especially concerned in its own class of manufactures; and it therefore followed that the laboratory researches were in some degree restricted to their own productions; but the great variety of material produced necessarily resulted in a certain amount of over-lapping, and a recognition of this fact led to arrangements being made some time ago for all experimental researches to be communicated to all departments. In addition, all the leading English and American engineering journals had been extracted, and the information so obtained was systematically recorded and indexed, and had constituted a valuable source of collateral information. With regard to methods of reporting results he did not advocate the use of stereotyped forms in every case, but he thought that for most of the tests now generally carried out standardized forms would be advantageous.

In the discussion Sir H. F. Donaldson said that as the Ordnance Factory at Woolwich had found that inter-departmental communication of research results was useful, it was to be hoped that the system would be followed in a wider field, and that private firms would assist in the co-ordination of research.

Professor Arnold said that at Sheffield the difficulties attending the co-ordination were being met by the establishment of a club consisting of three classes of members, namely, university graduates and associates, practical works, metallurgists, and the manufacturers.

Mr. Alexander Siemens spoke of the way in which the Siemens works in different countries co-operated in research work, and said that the plan which had been described was actually in operation between their establishments in London, Berlin, St. Petersburg and other places. But it was questionable if firms less intimately connected would take part in arrangements for making the results of their research generally available. There were firms who would not be willing to publish the results of their research, whilst they would gladly take advantage of the published results of what others had done.

Your correspondent is not alone in the opinion that, however desirable the co-ordination of research may be, it is not likely to be brought into operation in the immediate future, at all events, in England as far as manufacturing firms are

concerned, although something is to be hoped for in the direction of the collaboration of technical institutions and university laboratories for systematized research. The analytical and scientific chemist almost invariably publishes the results of his research, but this is not the case with the manufacturing chemist, who, as a rule, jealously guards against any divulgence of his processes, which lie, with some justification, regards as private property; and it is not to be expected that manufacturing engineer will be more ready to publish the results of his research than the manufacturing chemist, unless and until it can be demonstrated to him that he as well as others would benefit. The results of research undertaken for a definite object are just those which a private manufacturer or firm would be most unlikely to give away. There may be here and there an instance of the class last alluded to by Mr. Siemens; but vastly preponderating numbers of English manufacturers prefer to rely on their own experience and their own investigations.

The Supply of Tungsten in England

In *The Times* of the 13th August an anonymous correspondent stated that all the wolframite and scheelite produced in Cornwall or imported to Great Britain from the Colonies and abroad is sent to the Continent to be smelted into tungsten, of which a proportion is returned for the manufacture of electric lamps and a very large amount for the manufacture of tungsten steel. He further stated that there is no factory for producing the metal in this country, and pointed out that in the event of a European war in which England is involved the supply of tungsten would be cut off whilst the demand would largely increase.

But a week later *The Times* published a communication from a Luton firm stating that their works are now turning out many tons of ferro-tungsten a week in England, and are not only sending large supplies of that product to Sheffield but also to Russia, Austria, Germany and elsewhere.

Engineering Imports and Exports

The returns issued by the Board of Trade for the eight months ended on August 31 present figures which compare very satisfactorily with those for the corresponding period of 1912; but the statistics for the month of August exhibit considerable decreases in the value of most classes of engineering materials and products.

For the eight months the imports of iron and steel, including manufacturers, totalled £10,000,475, an increase of £1,038,248, and exports touched £36,841,732, an increase of £6,944,838. Other metals, including manufactures, were imported to the value of £21,571,818, an increase of £1,678,011, and were exported to the value of £8,949,586, an increase of £1,451,170. In electrical goods the imports amounted to £688,025, a rise of £67,118; and exports reached £3,477,685, an improvement of £764,671. Imports of machinery with a total of £4,022,334 show an increase of £415,517; and exports went up to £24,422,003, an advance of £3,260,284. The value of imports of new ships was only £24,223, a drop of £684; but exports rose to £8,318,951, an increase of £4,666,702.

The month of August, however, taken alone, shows extensive decreases. Imports of iron and steel were £9,018 less, and exports fell £51,583; imports of other metals decreased £254,215, and exports were £28,011 lower; electrical goods increased £16,781 in imports, but exports went down by £67,477; imports of machinery rose £3,021 and exports improved by £151,746; imports of new ships declined £2,354, while the exports increased by £2,466,506.

Sulphur, recovered, ton	5.	10.	0
Platinum, oz.	9.	5.	0

Tin opened £193 and rose smartly to £197 on the 4th, then dropping away to £193, recovering to £194.15.0 on the 16th then again falling away, till £190.5.8 was reached on the 22d. During the last week it rose to £195.5.0, but demand being satisfied, subsequently fell touching £191, and closing £189.5.8.

Copper opened at £71 and rose, exhibiting considerable strength, till by the 16th it had reached £75. It then fell to £72³/₄ by the 22d, rose sharply to £74 on the 23d, and after another dip to £72³/₈, rose to £75.10.0 by the 24th, but ultimately gave way to depression caused by labor trouble, and closes £72.10.6.

Lead opened at £20.15.0 and was inclined to go higher during the first week, but afterwards settled down, showing a maximum of 20³/₄ and a minimum of 19³/₄ (rumors of unexpected stocks over the greater part of the month. It closes £20.10.0.

Iron, Haematite opened 67¹/₂, but rose 67²/₃ by the 8th, then flat, afterwards irregular, till it reached 67²/₃ on the 16th and closes 67²/₃.

Scotch Pig opened 62¹/₂ and fell away, being 60¹/₂ by the 15th, then recovering slightly reached 60.0 by the 19th, and closes same price.

Cleveland opened 56¹/₂ but declined after the 3d, being 54¹/₂ on the 10th and 54¹/₃ on the 15th. It had recovered by the 19th to 54.0 and closes at that price.

better; imports of electrical goods increased £26,029, and exports advanced £215,670; machinery showed increases of £80,133 in imports and £373,181 in exports; new ships rose by £1,627 in imports, and exports improved to the extent of £732,965.

Tin has been fairly steady. Opening £186.0.0 it rose till the 12th when it touched £190.10.0, and then fell to £188, remaining for a week about this level till the 26th, when it again rose and closes £194.5.0.

Copper has not maintained the promise of a sharp rise which appeared to be probable in the middle of last month. Opening at £67.2.6 it reached £69.5.0 on the 9th, but fell to £68.15.0 by the 21st, but recovered and closes £71.0.0.

Hematite fell away considerably during the month. Opening at 71.9 it had dropped 2/- by the 6th, and another 2/- by the 21st. It closes at 67/-.

Scotch Pig opened 64/- and closes 62/-.

Cleveland opened 54/10 and did not show much activity till the end of the month. On the 24th it was 54/4, on the 28th 55/1½ and closes at 56/-.

Lead, opening high, £21.5.0, dropped to £19.3.4 on the 18th, and was £20 on the 22d, closes £20.15.0.

Synopsis of Recent Chemical and Metallurgical Literature

Electric Furnaces

Comparison Between Electric and Fuel Furnaces.—Anticipating the wider adoption of the electric furnace in metallurgical work within the next few years, Mr. F. LOUVRIER calls attention to the points of advantage in the electric furnace, in an article in the *Mexican Mining Journal* for September, 1913. Citing the fact that the electric furnace has "completely conquered the metallurgy of aluminium," and is used in the manufacture of steel, steel alloys and pig-iron, Mr. Louvriér makes the forecast that "at no distant date electricity will be applied in large scale to the treatment of all ores." The cause of this progress is ascribed to the superiority of the electric furnace over those now employed, the heat being produced electrically instead of by the combustion of fuel.

In considering fuel-burning furnaces, the author divides them into two classes: those in which the ore is in direct contact with the fuel, and others in which the ore is more or less completely separated from the fuel or products of combustion. It is evident that the thermic efficiency of the former type is greatly superior to that of the latter. By calculating the heat available from the combustion of carbon under operating conditions, and comparing it with that obtained in an electric furnace of the resistance type, the author reaches the conclusion that: "One electric horsepower per year is equal to 2700 kg of coke consumed in the ordinary furnaces." Comparing further the costs of the two thermic agents under different conditions, he arrives at the conclusion that the employment of electric furnaces is from two to five times as cheap as coke furnaces.

To this economy he adds the following advantages of the electric furnace:

- 1—Facility of regulating heat by simple handling of the electrodes or interrupters.
- 2—Constant production of the exact heat necessary, no matter what its intensity.

- 3—Elimination of the chilling of slags, so prejudicial in coke furnaces.

- 4—Easy treatment of all classes of ores, no matter how refractory.

- 5—Higher percentage of the recovery of metals as a consequence of (a) the non-oxidizing action of electric heat, which is produced without air or oxygen; and (b) the production of less and more fluid slag.

- 6—Decrease in manual labor due to less quantity of material to be handled, and because the ores can be treated as they come from the mines without crushing or briquetting.

- 7—Complete suppression of blowers and tuyeres.

- 8—Decrease in expenses of maintenance and repairs due to the maximum temperature being in the center of the ores treated and not on the walls of the furnace.

- 9—Production of purer metals; the electrical heat being chemically neutral and not introducing impurities contained in the usual fuels.

- 10—Possibility of operating profitably those mines situated in remote places, due to facility of transmitting electrical energy.

- 11—In all cases, decrease in transportation expenses, due to facility of treating ores at the mines.

- 12—Yields as high from small plants as from large ones.

Considering the above advantages as accruing in the case of metallurgical furnaces in which the ore and fuel are in contact, the author concludes that the economies of the electric furnace will be still further emphasized in the case of indirect firing. In the latter cases the following advantages of electric energy may be added to those enumerated above:

- 1—In the furnaces used for tin ores, one electric horse-power per year is equal to 3600 kg of coke, and yields a greater quantity of tin because the metal is neither oxidized nor carried away in the form of vapor.

- 2—In furnaces used for zinc reduction, one electric horse-power per year is equal to 7000 kg of coal, and the percentage obtained is not less than 95 per cent against 85 per cent by ordinary processes.

- 3—In the manufacture of crucible steel, one electric horse-power per year is equal to 18 tons of coke, this proportion being due to the high temperature required.

As the generation of one electric horsepower per year produced in gas engines calls for a consumption in coal of not more than 3855 kg, it can be concluded that in the treatment of tin ores, and, above all, of zinc ores, as well as in the manufacture of steel alloys and crucible steels, the use of electric furnaces is more advantageous, even should the electrical energy be produced by thermic engines consuming fuel.

Gold and Silver

Assay of Gold and Iridium in Black Sand.—Among the prizes offered in the Chemical, Metallurgical and Mining Society of South Africa, was one of twenty guineas by the Witwatersrand Co-operative Smelting Works, Ltd., for the best method of assaying gold in the presence of iridium and allied metals in such materials as black sand. The committee on awards selected two of the papers submitted as being superior to all others, although the committee was not fully satisfied that the authors had adduced sufficient evidence that the methods proposed would be wholly accurate and reliable. The following abstract of the two methods is taken from the July, 1913, *Journal of the Society*, in which the papers are published in full, with experimental data and bibliographies.

Method of James Gray.—From 0.5 to 2 A.T. of the material is assayed in the usual manner, and the button cupelled. The weight of this button gives the quantity of silver, gold and iridium. Owing to the tendency of the platinum metals to cause the button to scatter over the cupel, it may be necessary to add silver to the assay in order to obtain a single bead. In any event an excess of silver must be present prior to parting. The button is then flattened or rolled, and treated with hot concentrated sulphuric acid which dissolves the silver. The residue is washed and weighed, giving the weight of gold and

platinum metals. This residue is then dissolved in aqua regia, and the solution filtered to remove any insoluble platinum metals. The filtrate is made alkaline with caustic soda, the change from deep yellow color to almost white being easily noticed. From 10 to 20 cc. hydrogen peroxide (20 vols. quality) is then added, whereupon the gold comes down immediately as a black precipitate.

The mixture is then boiled for about ten minutes and filtered. After washing, it is run down in a crucible with borax, litharge and reducing agent, or scorified, and the resulting lead button thus obtained cupelled. The gold is weighed, and the difference in weight between it and the gold plus platinum metals gives the weight of the latter.

It is advisable to run a blank on pure gold simultaneously and add the loss thus observed to the weight of gold recovered. Ordinarily 99.5% of the gold is easily recovered. In the case of dilute solutions it is advisable to acidulate after the oxygen has been expelled by boiling.

The platinum metals may be recovered from the filtrate by means of sulphuretted hydrogen, and determined according to the methods of Leidie and Quennessen. The residue insoluble in aqua regia, as stated above, may be recovered in a convenient form by cupelling the filter paper.

Method of Chris Toombs.—One A.T. of the black sand is roasted at a scarcely perceptible dull red heat until sulphur-free. It is then fluxed as follows:

Black sand	1	A. T. (roasted)
Soda carbonate	2	A. T.
Borax	1½	A. T.
Litharge	1½	A. T.
Flour	4	gm.
Silver		q.s.

The mixture is placed in a paper bag and dropped into a red hot crucible. The assay is conducted at red heat until fusion is complete, and finished at nearly white heat. Wash with a mixture of litharge and flour, pour and cupel. Blanks of pure gold and silver should be cupelled at the same time. The resulting buttons are flattened, annealed, rolled and annealed, and parted in porcelain crucibles with dilute nitric acid (HNO_3 to $12\text{H}_2\text{O}$). Bring the acid to a boil, cool to about 80°C . and throw in the cornet. Action should be brisk but not violent. Heat to nearly boiling without actual ebullition; decant, wash and anneal carefully to avoid sticking iridium to crucible. Weigh gold and iridium together. Dissolve gold with 1 cc. 10% aqua regia in a long test tube; filter off the iridium, wash, dry and ignite over a bunsen burner. Weigh and make a deduction for the filter ash. Subtract this weight from that of the gold and iridium, obtaining the weight of fine gold in the 1 A. T. fused. Make proper correction as observed in the blank checks. If it is desired to recover and weigh the gold separately, the solution is neutralized with NaOH , added to a little NaCN solution, and precipitated with CuCl_2 . The precipitate is filtered, washed, scorified and cupelled.

Zinc Wafers for Precipitation of Cyanide Solution.—In our synopsis of current literature in April, 1913, page 219, we noted a new method of precipitation for gold solutions, making use of zinc wafers 1 to 2 in. long and $\frac{1}{4}$ to $\frac{1}{2}$ in. wide, instead of the usual zinc shavings. Excellent results were reported by Mr. John S. MacArthur. In the May, 1913, *Journal of the Chemical, Metallurgical and Mining Society of South Africa*, Mr. E. G. Baskett reports his experience with the use of this form of precipitation and gives decidedly unfavorable results, adding, however, that the conditions were not the same as those under which Mr. MacArthur obtained good results, and that more favorable conditions might give better results.

Mr. Baskett tried the method at the City and Suburban Mill, taking the special precaution to fill the lower compartments of the experimental box with zinc shavings in the usual manner. Four compartments were used for wafers and three for shavings, an intervening compartment being left empty and tapped at the side to obtain samples. With a flow of 10.5 tons solution per cu. ft. zinc per 24 hours, the extraction by

the wafers was but 35 per cent. On reducing the flow to 5.27 tons, the extraction was not improved, but fell to 31 per cent. White precipitate accumulated on the zinc wafers, and after 24 hours' running about 25 per cent. of the zinc surface was rendered inert. On cleaning up after ten days' working the wafers in the top compartment were found to have formed almost a solid mass with white precipitate. On examination of the wafers with a lens the whole surface was seen to be coated with a thin film of white precipitate which could not be removed by washing. The gold slime recovered contained only 1.41 per cent fine gold, the balance being white precipitate.

The experiment was repeated with stronger solutions coming from the sand vats, but was not more successful. After two days the whole precipitate appeared. The recovery was only 32 per cent.

Tin and Copper

The crude methods of smelting tin adopted by the natives of Mexico, in the vicinity of San Luis Potosi, are described in an article by Mr. GEORGE C. MASTER in the *Mining Magazine* for September, 1913. The work is done in a desultory manner by roving bands of tin miners who work in cooperation with the owners of ranches on whose lands tin deposits occur. The work is frequently profitable from the beginning of operations, as the miners work only exposed outcrops and quit when the vein pinches. The ore is crushed by hand to about $\frac{1}{4}$ -in. size, sorted and washed in a planilla and finally in a wooden batea. A planilla is a hole dug in the ground, about 5 ft. long, 3 ft. wide at the upper end and 2 ft. at the lower, with a sloping surface of from two to five degrees. At the lower narrow end, there is a cup-shaped hole in which the water collects. The depth is only a few inches below the surface, and stones are placed at the sides to prevent loss of water and mineral. The process of concentration consists in placing from 60 to 120 lb. of ore at the upper end of the planilla, and filling the role in the lower end with water. The latter is then thrown over the ore by means of a horn cup, and the lighter gangue is washed down the sloping surface, leaving the heavier cassiterite above. This process is repeated at least twice, after which the concentrate receives a final washing in a wooden batea, a form of concentrating pan. The concentrate thus obtained averages from 45 to 65% tin, according to conditions.

The blast furnace constructed by these natives is made of a hard stone cemented with clay called *tierra del fuego*. The dimensions of the furnace may be: height, 2 ft. 6 in.; top feed opening 5 in. square; front inside vertical, but back and sides sloping outward; inside diameter at bottom, 9 in. The bottom has a steep slope toward the open hearth in front, the latter being merely an excavation with a clay-lined floor. The blast is produced from two bellows, worked alternately by two men. The bellows are made of ox-hide; the nozzles unite, forming one thyrer made of a piece of iron pipe, placed about 8 in. above the furnace bottom. Before commencing operations the furnace and hearth are lined with clay, and when dry, a charcoal fire is started. A light blast is admitted, and when the temperature has risen sufficiently, the moistened charge is fed, in the proportion of one part concentrate to three parts charcoal, by weight. When the furnace is smelting well, some hard-lead obtained from previous smelting operations, is added. As much as 450 lb. concentrate may be smelted at one time, and when the operation is nearly finished, the slag is broken to 1 in. and resmelted. The treatment of 450 lb. concentrate requires 16 hours. The loss is approximately 10%. The tin is run onto the hearth every few minutes, and later rolled into parcels of 25 lb. weight. The metal contains from 90 to 96% tin. The cost for smelting 450 lb. concentrates is given at 10.20 pesos, or about \$8 gold.

Electric Smelting of Tin Ore.—Particulars concerning some experiments made by the Grondal-Kjellin Co., of London, in smelting tin ores in Cornwall, are contained in the *Revue Industrielle*. Pure ores yielded metal of 98% purity, and Bolivian ores containing about 50% tin and 15% iron, gave

metal of 92 to 97% purity. The latter could be further refined to a purity of 99.75% by blowing air through the molten mass. The energy consumed was 1700 kw-hours per ton; but this may be reduced to 1400 kw-hours, with an efficiency of 55%, by using two furnaces, one for the production of high grade metal and the other for treatment of rich slags. The process may be commercially profitable where hydroelectric power is available.

Copper Smelting at Messina, Northern Transvaal.—Reverberatory smelting of copper concentrates is in progress at the Messina copper mines in the northern Transvaal. According to the *South African Mining Journal*, the furnaces are small having a hearth area of only 23 ft. by 11½ ft. The capacity of each furnace is 20 tons of ore in 24 hours, and the fuel consumption is 7 to 8 tons of coal. Local coal has been found suitable for the purpose, and the limestone necessary for fluxing is also found in the neighborhood of the mines. The first matte produced contained 65% copper, but later operations were conducted to yield a matte of 50% copper. Additions are being made in the way of roasting furnaces, and it is expected that ultimately converters will be added.

Ore Dressing

Need of Better Classification.—In considering the improvements in ore treatment necessary to permit the utilization of lower grade ores, Prof. ROBERT H. RICHARDS, of Boston, Mass., believes that better and more extensive classification is one of the requisites. His paper on the subject appears in the September *Bulletin* of the American Institute of Mining Engineers. The following incident illustrates Prof. Richards' contention: A three-pocket cone classifier in a small mill had a feed ranging from 2 to 0 mm., and supplied four Wilfley tables. The first spigot had about all the sand and a great deal of slime; the other spigots and the overflow were about all slime. As a result all tables carried wide bands of slime and their tailings were charged with fine free mineral. The mill work was greatly handicapped by lack of good classification, for it is a proved fact that when the feed to a Wilfley table carries slime, then the tailing will carry fine free mineral. When this same ore was tested in the laboratory, it yielded easily 12 spigot products, all of which, when fed to Wilfley tables, gave no bands of slime on the tables; and free fine mineral was absent from the tailings of the coarser tables, and present only in small quantity in a few of the finer.

The benefit of this extended classification will be apparent from the following tables, showing the relative sizes of quartz and galena in the spigot products and overflows from a 3-spigot and a 12-spigot classifier.

Three-spigot Classifier

I
—of the quartz
3.5

Spigot	Quartz. Diameter, Millimeters	is galena. Diameter, Millimeters
1	6.30 to 2.15	6.30 to 0.614
2	2.15 to 0.73	0.614 to 0.208
3	0.73 to 0.25	0.208 to 0.0715
Overflow	0.25 to 0.00	0.0715 to 0.0000

Twelve-spigot Classifier

1	6.30 to 4.79	6.30 to 1.37
2	4.79 to 3.66	1.37 to 1.05
3	3.66 to 2.80	1.05 to 0.80
4	2.80 to 2.14	0.80 to 0.61
5	2.14 to 1.63	0.61 to 0.47
6	1.63 to 1.26	0.47 to 0.36
7	1.26 to 0.96	0.36 to 0.27
8	0.96 to 0.73	0.27 to 0.21
9	0.73 to 0.56	0.21 to 0.16
10	0.56 to 0.43	0.16 to 0.12
11	0.43 to 0.33	0.12 to 0.094
12	0.33 to 0.25	0.094 to 0.071
Overflow	0.25 to 0.00	0.071 to 0.000

Here we have limited and extended classifications of the same material, say quartz and galena. With free settling, the classified products, after the first spigot and before the final overflow, will contain grains where the quartz is approximately 3.5 times the galena in diameter. If we compare any two products, eliminating the first and last, both of which require special treatment, it will be clear that a Wilfley table treating spigot 2 of the three-spigot classifier, which has to separate 0.614 to 0.208 mm. galena from 2.15 to 0.73 mm. quartz, will not have so easy a task as the table which treats spigot 2 from the twelve-spigot classifier and has to separate 1.37 to 1.05 mm. galena from 4.79 to 3.66 mm. quartz. The same opinion holds with regard to the third spigot of the three-spigot classifier and the twelfth spigot of the twelve-spigot classifier; and is true also of all intermediate spigots.

"Next, let us see what a long classifier with many spigots will do, which a short classifier cannot do. We shall find, as follow on down from the coarser spigots toward the finer, that Wilfley tables will yield tailing products free from fine free mineral and, therefore, at the minimum assay that can be obtained without further regrinding. After a time, however, we shall arrive at a spigot where the heavy mineral in the spigot is the same size as the normal size of Wilfley fine free mineral. Then the Wilfley table breaks down, can no longer yield clean tailing, and the vanner should take its place, because the fine free mineral in the vanner tailing is smaller than that in the Wilfley table. If we follow still further down the spigots we shall find a spigot or the final overflow where the size of the heavy mineral is the same as the size of the fine free mineral in the vanner tailing. Then the vanner breaks down, can no longer yield clean tailing, and we go to the new great Anaconda round table, which takes all the rest down to the size of the heavy mineral that floats away in a slow-moving stream of water. With this the methods of water-gravity separation of fine material, that are now in sight, close."

The author goes on to show that the slime is not unduly diluted by using so many pockets in a classifier, provided steady and uniform feed is supplied. He concludes by showing the enormous sums that could be saved by good classification, and says "that we need better classification, more classification, and higher-priced, broader-minded men to see that the greatest benefit is derived from the improved machinery."

Recent Chemical and Metallurgical Patents

Iron and Steel

The preliminary preparation of fine ore and flue dust for smelting in the blast furnace, is the subject of a patent granted to Messrs. HARTLEY C. WOLLE and EDWARD F. KENNEY, of Westmont Borough, Pa. The invention consists essentially in compressing fine materials into a compact mass by passing a steady and uniform feed of these materials between rigid rolls, forming a thin sheet which subsequently breaks into flakes suitable for blast furnace work. The inventors' idea is to treat ore and flue dust that is finer than 1/16 or 1/8-in. mesh, and pass the same between rolls set 1/8 or 1/4 in. apart. The rolling pressure compacts the loose material, giving a product which has a greater surface density than exists in its interior portion, and which is at the same time porous enough for blast furnace smelting. Actual experiments with natural ores show that moisture must be present within the limits of three and eleven per cent. (1,073,381, Sept. 16, 1913.)

Preheating Air for Metallurgical Furnaces.—In Fig. 1 is illustrated the embodiment of an invention of Messrs. JOHN W. HAMILTON, JR., and JOHN W. JOHNSON, of Coatesville, Pa., designed to preheat air in a manner that will eliminate the use of costly checkerwork. The heat radiated at the hearth of the furnace is utilized to bring the air to the proper temperature, particularly for use in gas-burning furnaces. Referring to the figures, A is a furnace of the continuous type for heating ingots and blooms *x*. B is the heating chamber and C is the outlet to the stack. D is the inlet flue for gas,

and E is an air duct communicating with D by means of *e*. The ingots or blooms travel on water-cooled rails *b*, *b*, which are supported at intervals on piers *b*². The hearth *B*¹ is directly under the main combustion chamber of the furnace. Located under the hearth are two air chambers I, side by side,

FIG. 1.—METHOD OF PREHEATING AIR

and there is only one layer of fire brick between these chambers and the combustion chamber. The plan of the air chambers is shown more clearly in the lower diagram of Fig. 1. Air is forced from a fan or blower into the passage *n*, traversing the chambers J and I, and issuing at *n*¹ to the air chamber E which communicates with the gas flue D, where it is mixed with gas prior to combustion. Auxiliary heated air

FIGS. 2 AND 3.—OPEN-HEARTH FURNACE CONSTRUCTION

passes through the straight side chambers J¹, entering at *m* and issuing at *m*¹ to the chamber M located above the outlet door of the furnace, and passing into the combustion chamber by passages *m*². The amount of gas and air can be controlled by any suitable valve mechanism. (1,072,331, Sept. 2, 1913.)

Air-cooled Blast Furnace.—RICHARD H. STEVENS of Mun-nace by a current of air. This air is furnished by the Low-hall, Pa., patents the idea of cooling the walls of a blast furn-ing engines or compressors, passes through the hollow metal jackets which form the shaft lining and proceeds in this pre-heated condition to the hot blast stoves, where it receives the high temperature required by the hot blast. (1,074,097, Sept. 23, 1913.)

Siemens-Martin Furnace.—When it is desired to recover and work up volatile metals or compounds contained in iron or in ferric oxide, KURT ALBERT of Wiesbaden, Germany, recommends to divide the open-hearth process into two periods, during the first of which the valuable volatile matters are recovered in an additional chamber arranged like the checker chambers. During the second period the steel is finished in the usual way and is safe from any admixture of undesirable elements, and furthermore the chambers will not become choked up. Thus the volatile metals or their oxides

FIGS. 4 AND 5.—OPEN-HEARTH CONSTRUCTION

from galvanized iron, tiniferous calcined pyrites and the like can be recovered. Figs. 2 and 3 show one arrangement of applying this process. The gases containing the volatile matter are drawn by a fan through the recuperator R and filtered in bags or other devices not shown. The chambers K₁ and K₂, also K₃ and K₄, serve for heating gas and air respectively. In Figs. 4 and 5 two additional air chambers, L and L¹, are shown through which the gases of the first period may pass, and in another arrangement shown in the patent specification the same purpose is aimed at by building two chambers, laterally outside of the regular furnace structure. The partitions of these auxiliary air chambers can be closed, each one individually, by a damper. This arrangement provides for a cleaning of the chambers while the furnace is working. (1,073,053, Sept. 23, 1913.)

Refining Iron and Steel by Means of Ferrochromium Alloy.—JOSEF BECHEL of Wengern-Ruhr, Germany, claims that the known objectionable formation of carbides when alloying commercial ferrochromium with steel will be avoided

when the ferrochromium contains neither carbides nor oxides. When free from these elements it has a much lower melting point than ferrochromium produced by the ordinary electro-metallurgical process [2]. To this end the chromium alloys are treated for protection from oxidation by alloying with silicon, aluminum, calcium, barium or an alloy of iron, chromium and aluminium. This helps an expeditious and uniform distribution of the chromium in the metal bath. (1,071,873, Sept. 2, 1913.)

Lead and Zinc.

Process for Sublimed White Lead.—In the manufacture of sublimed white lead from ores and concentrates, difficulties are encountered in subliming all of the metal and in producing a pigment of uniform white color. To overcome these obstacles Mr. ERNEST E. BANES, of Strathfield, near Sydney, N. S. W., has patented certain apparatus and method of operating the same, whereby he claims complete sublimation of the lead, and zinc if contained in the ore, and the production of a pigment of uniform white color and consumption. In carrying out the invention, finely divided lead sulphide ore or concentrate is fed continuously into a furnace through a blow-pipeflame introduced through a tuyere opening. The particles are thus dispersed, and complete volatilization occurs in the enveloping oxidizing atmosphere, matting and slagging being avoided. The fume passes from the furnace and is collected in a suitable bag house.

The material to be treated is ground preferably finer than 40-mesh, and introduced into the furnace in a blast of air and combustible gas, through two or more opposed blow pipes, which are directed toward a point a few inches above the level of the contained fuel bed. Hot air is blown through tuyeres toward the same point, and supplementary cold air enters the furnace tangentially through other tuyeres above the hot-air tuyeres. A plant for the manufacture of sublimed white lead according to this inventor's process would consist of a shaft furnace fitted with tuyeres as described and containing a bed of fuel; a gas producer; an air blower forcing air through a preheating chamber in the furnace flue; cooling chambers and bag house.

A sectional view of the furnace is given in Fig. 6, and the ore-feeding tuyere is shown in Fig. 7. Within the furnace a fuel bed 68 rests on a grate 13. Fire box and ash pit are accessible through close-fitting doors. Ore-feeding tuyeres are oppositely disposed, one being shown at 43. Hot-air tuyeres are placed at 45 and cold-air tuyeres at 47. The ore-feeding tuyere, shown in Fig. 7, consists of a rotating auger 58 which advances the ore fed at 62 to the nozzle where it is dispersed by a whirling jet of air entering at 53. The gas port is at 50. The rate of feed of galena is regulated by the speed at which the auger is rotated, and bears a fixed relation to the air pressure and gas volume delivered to the nozzle. This fixed relationship between supply of ore, gas and air is a matter

FIG. 6.—FURNACE FOR SUBLIMED WHITE LEAD

FIG. 7.—ORE-FEEDING TUYERE

of importance in the uniform operation of the furnace. The non-volatile elements contained in the ore fall as dust onto the fuel bed or are collected in the dust chambers. By grading the feed so that it contains a uniform percentage of galena, the product of the operation will be uniform. (1,073,462, Sept. 16, 1913.)

Lead Oxide for Storage Battery Plates.—An improved method of making amorphous lead oxide of low specific gravity and density, suitable for use in battery plates, is disclosed in a patent granted to Messrs. OLIVER W. BROWN and ALPHEUS R. NESS, of Bloomington, Ind. The product of their process is said to be more plastic and of higher tensile strength than similar pastes made from crystalline oxides. The required amorphous condition is obtained by heating basic or neutral lead carbonate, lead sponge, amorphous litharge or metallic lead at a temperature between 425 deg. C. and 440 deg. C. for a period of from three to three and one-half hours. (1,072,205, Sept. 2, 1913.)

Extraction of Zinc from Slags.—Processes for the extraction of zinc from furnace slags have been proposed, based on mixing the slag with a reducing medium, briquetting and re-treating in a furnace, whereby the zinc was volatilized and

FIG. 8.—AGITATOR FOR ORE SLIME

collected as oxide. A novel process for treating furnace slags while in the molten condition, and removing the contained zinc oxide, is patented by ADOLPHE H. DESGRAZ, of Hanover, Germany. The operation is carried out in a reverberatory furnace, and depends on the principle that zinc oxide can be displaced from its combination with the ferro-silicates of the slag by adding a strong base, such as calcium oxide. The quantity of calcium oxide added to a molten slag is such as to give the resulting slag a lime content of from 25% to 35%. The zinc oxide being volatile, is collected in any suitable manner. (1,072,209, Sept. 2, 1913.)

Gold and Silver.

Agitating Apparatus.—A device for agitating, mixing and aerating mixtures of solid and liquid, such as ore slime

and cyanide solution, is shown in section and plan in Fig. 2, being the invention of Mr. WALTER E. TRENT, of Reno, Nev. It comprises a hollow convolute distributing arm, provided with a series of outlet nozzles projecting from the forward surface of the arm and extending in a direction opposite to the travel of the distributing arm. Its principal object is to overcome the objections to similar devices in which the distributing arms extend radially from the center. Among such objections is the difficulty of starting the agitating mechanism after it has been allowed to remain at rest for a period, due to the packing of solid material around the arms.

Referring to Fig. 8 (p. 656) the material to be treated is fed into the receiving tank in any suitable manner, until it overflows the pipe 16 and submerges the tubular arm 14. The pump 15 is then started and the slime is circulated through the pipe 18 into the distributing reservoir 10, and thence through the arm 14 and nozzles 14'. Motion will be imparted to the arm, which will rotate and direct streams of slime from the nozzles to every part of the tank. Owing to the arrangement of the arm and nozzles, the material agitated will not be banked in front of the arm following, as the nozzles project from the forward surface of the arm. (1,073,878, Sept. 23, 1913.)

Chloridizing-Roasting of Ores.—Apparatus for applying a chloridizing roast to ores for the purpose of rendering their base and precious metals soluble, is shown in Figs. 9 and 10, being the patented invention of Mr. NIELS C. CHRISTENSEN, of Salt Lake City, Utah. The object of the apparatus and process is to treat an ore moistened with a saturated solution of alkali and alkaline earth chlorides, by successively roasting,

the mechanism 10. Beneath the deck is an annular sealed space divided into two portions 11 and 12, by the wide partitions 13 and 14. The part 11 is beneath the cooling portion of the hearth, and the part 12 beneath the roasting portion. These spaces are suitably sealed from the outside air. Above the deck is a stationary hood 17-18, divided into two chambers 20 and 21 by the partition 22; the part 20 is above the cooling stage of the deck and the part 21 is above the roasting stage.

The ore is charged onto the slowly revolving, perforated hearth in a uniform layer from the hopper 25, and is removed by the screw conveyor 26. The space above the roasting deck is connected by pipe 42 with the condensing tower 41. The fan 28 is connected with the space 11 beneath the cooling portion of the deck; and the fan 31 is similarly connected with the space 20 above the cooling portion, and also by pipes 33, 34

FIG. 10.—SECTION OF CHLORIDIZING ROASTING FURNACE

FIG. 9.—PLAN OF CHLORIDIZING ROASTING FURNACE

cooling and leaching. Features of the furnace are the means provided for conserving heat and for recovering the valuable constituents of the roaster gases.

Referring to Fig. 9, which is a plan of the furnace, and Fig. 10, which is a vertical section on the line 2-2 of Fig. 9, the numeral 1 indicates an annular deck with cast-iron frame 2, carrying a perforated grate 3. The deck and frame revolve, being driven by the rope 10' which encircles the deck and

and 35, with the combustion chamber 36 which opens into the space 12 beneath the roasting portion of the deck.

In operation, the ore is fed from the hopper 25, onto the revolving hearth, and passes successively through the roasting and cooling portions 12-21 and 11-20. The fan 28 forces cold air through ore in the cooling chamber, and extracts heat from the cooling ore. This heated air is drawn by fan 31 from above the cooling ore, and delivered by pipes 33, 34 and 35 through the combustion chamber 36 and thence beneath the roasting portion of the hearth and upward through the layer of ore.

From the space above the roasting ore the gases are drawn into the condensing tower. The metallurgical features of the process are treated more fully on page 605. (1,075,011, Oct. 7, 1913.)

Vacuum Filters.

Continuous Vacuum Filter for Thickening Pulp.—Among the various devices tried at Anaconda for thickening slime pulp prior to concentration was the Garred filter, the invention of ULYSSES A. GARRED, of Anaconda, Mont. The filter may be briefly described as a "fixed" type of leaf filter, constantly submerged in the slime pulp, the filtering being accomplished by the aid of a vacuum, and the cake thus formed being discharged by a reverse pressure of water. The novel feature lies in the arrangement whereby the operation of a series of batteries of such filters is automatically controlled by valves which prescribe the periods of time during which filtering and discharging are continued. The operation is thus made continuous; the filter frame is not removed from the tank; a large volume of water is withdrawn, and the thickened slime discharged from the leaves settles to the bottom of the tank and is withdrawn through suitable openings. (1,072,111, Sept. 2, 1913.)

Metallurgical Furnaces

Zinc Ore Roasting Furnace.—An improvement in mechanically rabbled roasting furnaces, particularly in the type in which sets of rabblers attached to an endless cable pass first through the furnace and then in the opposite direction outside the furnace, has been patented by MR. FRANCIS CURNOW, of Pittsburg, Kans. Since it is not necessary to operate such furnaces continuously, an automatic mechanism is provided for stopping the rabblers, by means of a tripping device which is actuated by the rable when it arrives at a predetermined point. An adjustable timing device is arranged to start the rabblers again after a predetermined interval of rest. (1,072,920, Sept. 9, 1913.)

An automatic charging device for roasting furnaces of the superimposed hearth type is shown in Fig. 11, being the patented invention of LUDWIG SINGER, of Bochum, Germany. In the crown 1 of the furnace 2 are arranged a number of

FIG. 11.—AUTOMATIC CHARGING DEVICE FOR ROASTING FURNACES

stationary, bottomless charging vessels 13 seated in a cover plate 4. These vessels are closed at their lower end by means of a false bottom secured to the central shaft and rotating therewith. The false bottom is provided with one or more openings 20 designed to register with the bottomless charging vessels during the revolution of the shaft. The volume of ore to be delivered to the furnace may be regulated by altering the

FIG. 12.—ELECTRIC ARC PROCESS FOR PRODUCTION OF BORON AND HYDROCHLORIC ACID

size of the charging vessels. In operation, the rake 21 delivers ore to the charging vessels which retain their charge until an opening in the false bottom allows the material to fall onto the upper hearth of the furnace. The arms of the rake 21 are related to the openings 20 in such a manner as to prevent the simultaneous filling and emptying of the charging vessels

A sand seal formed by the annular walls 8 and 9 prevents the escape of heat and gas from the upper hearth of the furnace. (1,071,962, Sept. 2, 1913.)

Electric Arc Reactions

Boron and Hydrochloric Acid.—JOSEPH L. R. HAYDEN of Schenectady, N. Y., assigns to the General Electric Co. a process and apparatus for producing chemical reactions in an electric arc. Fig. 12 indicates how boric chloride and hydrogen are caused to react in producing boron and hydrochloric acid. The arc is formed between a cathode of easily vaporizable material, such as mercury, zinc, cadmium or alloys, and an anode of perforated copper. The hydrogen for instance passes over the boric chloride (17) through the chamber 3, in which the arc is maintained, between mercury (1) and the copper (2). It carries enough of the liquid off for reaction. The products are cooled in the water-jacketed pipe (8). The excess of liquid returns through pipe (14) into the reaction chamber, the gas can be exhausted through pipe (13). The observations of the inventor indicate that the chemical activity is due, in part at least, to an electrical effect which is distinct from the purely thermal action of the arc. (1,072,945, Sept. 9, 1913.)

Acid-Proof Castings

Silicon Article.—THOMAS B. ALLEN of Niagara Falls, N. Y., assigns to the Carborundum Company an interesting process of pouring articles of metallic silicon. The silicon and its alloys made in the electric furnace are said to contain silicon dioxide, nitrogen and oxygen, all in dissolved form. This fact has made castings of the metal very spongy and produced blow holes, and mechanically unsound castings. A large number of substances are able to combine with these impurities and produce stronger, denser and more perfect castings. Among the substances are the alkali and alkaline earth metals, magnesium, vanadium, titanium, aluminum, boron, etc. The inventor prefers metals like calcium, magnesium or vanadium which deoxidize and also remove nitrogen. Silicon is tapped from the electric furnace into a graphite crucible and held molten for one or two hours in a coke or oil furnace. To prevent losses, the surface is covered with a layer of coke. When the silicon is in a very fluid condition, from 0.5 to 3% of magnesium are added. When the magnesium produces no further reaction the silicon is poured, preferably from the bottom of the crucible. The mold is made of dry sand, and its surface coated with talc. The metal shows a marked absence of blow holes and flow marks, and consists of very fine crystals; the articles have considerable mechanical strength. The castings have high acid resisting properties, and are particularly useful as chemical ware. (1,073,560, Sept. 16, 1913.)

Alloys

An aluminium alloy capable of being rolled into thin sheets or otherwise manipulated as a malleable metal, is patented by WILLIAM A. McADAMS, of Bay Shore, N. Y. It contains aluminum, zinc and copper in such proportions that the aluminum will be substantially five times by weight the amount of zinc, and the zinc substantially five times by weight the amount of copper. The aluminum is first melted, and into this molten metal the copper is added in a cold state, preferably in the form of wire. This mixture is then cooled to a dull red, after which the zinc is added in the form of slabs, and the mixture stirred and cast. (1,072,017, Sept. 2, 1913.)

The Alaska Gold Mines company has 1200 acres of ground on which 50,000,000 tons of \$1.50 ore have been developed. In the estimation of the company's engineers there is a total of 200,000,000 tons of such ore. The initial plant to be installed for the treatment of this ore will have a capacity of 6000 tons per day, and it is expected that a net profit of 75 cents per ton will be made. The ore will be mined through two tunnels driven on the 1600 and 2300 levels. The latter will be the main outlet and will be 10,000 ft. long. Eight thousand horsepower will be developed in two hydroelectric plants.

Regulating the Temperature of Liquids

In many chemical and industrial plants it is important to maintain water or any other liquid in a tank, boiler, etc., at a certain predetermined temperature. This is generally done by supplying through a valve, more or less steam (or hot water) to the tank or heating coil.

The problem of automatic temperature control is then simply to regulate the valve automatically in such a way that it admits just the right amount of steam which is required to maintain the temperature in the tank at the fixed value.

This problem is solved by the Sarco water temperature regulator in the following simple way:

As shown in Fig. 1, there are three principal parts: First, *A*, the thermostatic element which is inserted in the boiler or tank and which is thereby affected by the temperature of the liquid in the tank. The effect produced by any temperature variation in the thermostatic element *A* is transmitted from it

extends downwards into the tube *A* can be regulated by means of the screw head *C*.

From this thermostatic element *A* a piece of fine copper tubing *D* passes to the controller *G* which also contains a piece of corrugated copper tubing *F*. This corrugated copper tubing *F* is also capable of compression.

The thermostatic element *A*, the connecting tube *D*, and the controller *G* form one hermetically closed chamber

If now the temperature in the tank should rise, the temperature of *A* also rises, and the oil in *A* expands. The pressure exerted is transmitted from *A* through *D* to the controller *G* (all three forming together one chamber) and the corrugated compressible copper tube *F* in *G* is compressed. This forces out the piston *I* and tends to close the valve *K*. The spiral springs *E* and *J* operating in the opposite direction tend to keep the valve open.

Hence, as a result of an increase of temperature in the tank, the valve *K* will close partly until a new state of equilibrium is reached, so as to admit less steam to the tank and keep the temperature in the tank at the predetermined value.

Of course, should the temperature in the tank tend to fall, the regulator acts in the reverse manner, opening the valve *K* further, etc.

FIG. 2—EXTERIOR VIEW OF WATER-TEMPERATURE RECORDER

The regulator is capable of quite delicate adjustment by means of the screw *C*, which permits to expand or contract the compressible copper tube *B* and thereby decrease or increase the space in which the oil is confined.

An exterior view of the whole regulator is shown in Fig. 2. Some of the chief advantages claimed for the Sarco water temperature regulator are the compactness and simplicity of its design, the fact that it is wholly self-contained and requires no exterior operating means such as compressed air and the avoidance of rubber or leather diaphragms or of metal diaphragms. It is built by the Sarco Engineering Company, 110 Broad Street, New York City.

The Acimet Valve

The economical importance and absolute necessity of sulphuric acid and other corrosive liquids in many lines of manufacture, and the great annoyance and expense incurred in controlling and distributing these solutions by means

of pipe lines, valves, etc., have given great importance to the problem of devising pipe and valves that would resist corrosion.

The solution of the pipe question was comparatively easy, as lead pipe was available for the purpose, and later lead-lined pipe entered this field, but the valve proposition was far more difficult to solve.

The approach to the solution was somewhat crude, as is often the case, but the ultimate result was most gratifying, producing as it did the

Acimet valve, for which its makers claim not only high efficiency, but relative inexpensiveness.

Some of the very first Acimet valves made for experimental

FIG. 1.—DIAGRAM OF WATER-TEMPERATURE REGULATOR

to the second principal part *G*, the controller element, and this acts directly on the third principal part, the valve *K*, which controls the admission of steam to the tank and thereby controls the temperature in the tank. Let us now see how this transmission of effects is brought about.

The thermostatic element *A* is a tubular receptacle containing a heavy hydro-carbon oil into which is inserted at the top a piece of corrugated copper tubing *B*. This corrugated copper tubing is compressible and its length or the depth to which it

VALVE CONSTRUCTION

purposes are still in service, having been used continuously for more than eight years, during which time they have required no repairs or attention except occasional packing.

When more recently the question of placing the Acimet valve on the market came up for consideration, it was realized that a symmetrical and harmonious design would be desirable. After much experimenting the formula for Acimet metal was developed and a mixture produced which has all the wearing qualities of sheet lead, and which can be cast and machined the same as brass or iron, and through an interesting method of reinforcing (as shown in the illustration), it is made stiff and rigid, so that no distortion of any kind takes place under any strain due to either pressure or piping.

The Acimet valve, the novel and original features of which are covered by letters patent, is made by the Cleveland Brass Mfg. Company (formerly the Cleveland Bronze & Brass Works), of Cleveland, Ohio.

Automatic Release Pen Lifter for Recording Instruments

The Industrial Instrument Company, of Foxboro, Mass., which manufactures an extensive line of recording instruments, has just perfected a new attachment for their recorders, for which patents are pending.

This attachment is called an automatic release pen lifter and is shown in the adjoining illustration. It can be attached to any Foxboro recorder. It is a very simple device consisting of a German silver strip mounted on a special holder, which is inserted under a screw head which holds the chart disc. A slight pressure on a small lever brings the strip up against the pen arm and lifts the pen from the chart. Friction holds it in the raised position, thus giving the operator free use of both hands for removing the used chart and supplying a new one. When the door is closed, the pen arm is automatically released

AUTOMATIC RELEASE PEN LIFTER

and the pen returns to its marking position on the chart. This automatic feature makes it impossible for the operator to forget and leave the instrument out of commission.

The device is very neat, and not only helps in the changing of charts but, what is more important, does away entirely with the necessity of handling the pen arm, with possibility of affecting the adjustment due to a slip or accidental strain. It also prevents accidents commonly resulting in spreading ink where it does not belong and is not desired.

Seamless Lap-Welded Steel Kettle

The adjoining illustration shows a large seamless lap-welded boiling kettle made by the American Welding Company, of Cardonvale, Pa., for a prominent chemical company of this country. It is made of rolled steel plates bent into the desired shape and size. The inside diameter is 8 feet, the inside

depth 8 ft. 6 in., the width of the flange $4\frac{1}{2}$ in. The shell consists of $\frac{3}{4}$ -in. steel plate, the convex bottom is also $\frac{3}{4}$ in. thick. The capacity is 3000 gallons, the weight 9500 lb.

One of the great advantages of kettles made from rolled plate steel is that the construction is much lighter and stronger than that of kettles made from cast iron; as a result of the thinner walls the heat transmission is very much better. Further the plate-steel kettle can be thoroughly annealed so as to remove all inherent strains, while it is impossible to eliminate the strains in a cast-iron kettle.

The seams are heated by furnaces operated with water gas and are welded by either hammer impact or hydraulic power, forming a seamless weld about equivalent in strength and thickness to the plate itself, the surface of the weld being smooth on both sides. As the edges of the plates are lapped sufficiently to form a perfect weld no material other than

BOILING KETTLE

the edges of the plates is used in making the weld. Consequently a perfect lap-weld thus made is the same as the plate so that corrosion will not act upon the weld more rapidly than upon the body of the plate.

In the standard design of the American Welding Company the shell of the kettle at the top is flanged outward forming a right-angled flange. Supporting brackets of either cast iron, pressed or cast steel may be secured to the shell if preferred.

The kettle may be supported, however, by a specially designed ring base resting upon the furnace walls, the kettle being supported by its flange resting upon the ring. The advantage of such a method of support is obvious, as the shell of the kettle is kept intact and free from objectionable rivets. Replacements can be made at a minimum cost.

These kettles are made either plain or jacketed.

A metallographic study of the ores from the Silverton district, Colorado, is being made by Mr. B. F. Laney, under the joint direction of the Geological Survey and Bureau of Mines.

Multiple-Effect Water Still

The multiple-effect water stills, built by the Pure Water Apparatus Company, Abbott Building, Philadelphia, Pa., are interesting in various ways.

First, an essential difference from the ordinary multiple-effect evaporator may be pointed out which is indicated by the fact that the Pure Water Apparatus Company builds multiple-effect stills with up to 20 effects.

The apparatus consists of a series of similar cells through which the heat units of the primary steam pass in succession, in each cell evaporating water to be purified and producing distilled water by the condensation of the steam which has brought this heat from the previous cell, thus producing at each exchange an additional quantity of distillate by the re-use of the original heat.

This process in itself is not new. The new feature is that while in the process just described a certain amount of the heat is lost by radiation from the outside of each cell, this loss of heat by radiation of each cell is automatically compensated by the addition of just the correct amount of steam to each cell in the Pure Water Apparatus Company's system.

Let us assume an eight-effect still with an initial steam pressure of forty pounds. This steam enters the first condenser and is condensed, and the water surrounding the condenser is evaporated and raised in temperature until a pressure of say twenty-five pounds is reached. But since we began with a pressure of forty pounds and want to use eight effects, we want to get at this point a pressure of thirty-five pounds. In order to get this additional pressure, steam is now let into the header from the main by a reinforcing valve (a patented feature which automatically maintains the desired pressure in each of the cells).

This process is repeated from cell to cell until the final cell is reached and the pressure and heat in the steam are fully utilized, the heat finally emerging as steam at atmospheric pressure from the last cell.

Each condenser is provided with a vent cock by means of which, together with other devices, the poisonous gases and air in this steam are separated from the steam and allowed to escape.

A coke compartment is provided to purify the steam and also to prevent entrained water being carried to the next condenser in the series. The distillate from all the cells passes through a heat exchange where it meets the cool incoming water to be used for supplying the various cells, and conserving the heat for further use in the stills.

From the heat exchange the accumulated distillate is passed

FIG. 1—STILL FOR SOLSCHEID WATER CO., KANSAS, MO.

through a charcoal cell which deodorizes the water, making it sweet and palatable.

After the distillate is finally collected and passed through the charcoal cell it is totally devoid of all deleterious and obnoxious gases. The high temperature at which the distillate is in contact with the steam in these stills makes it impossible to reabsorb these gases so that with this system aeration to destroy them is unnecessary. Aeration is a makeshift at best, the old theory being that contact with the atmosphere would remove these gases; as a matter of fact, contact with the sur-

rounding air simply changes their nature, but they still remain as impurities.

Still another important feature is the pretreatment apparatus or water softener which removes all scale-forming ingredients from the incoming water before it enters the still. This pretreatment employs heat alone as the purifying agent and it is this system of softening water that assures continued economy under constant operation.

There are numbers of instances where these stills are operating after many years' service and no trouble has been en-

FIG. 2—INSTALLATION AT CURACOA, D. W. I.

countered due to scaling, using some of the worst alkali waters in the southwest.

This system has many other minor improvements which make for such economy of operation on a large scale that it is claimed to produce as many as fifty to eighty tons of chemically pure water per ton of coal—it being understood that the coal will evaporate in the boilers not less than eight pounds of water to one pound of coal.

Fig. 1 shows a small-size still which is at present in very successful operation for the Solscheid Water Co., Kansas, Mo. It is a 2500-gallon per 24-hour outfit of the two-effect type, giving about 1.7 lbs. of distillate per pound of live steam entering the initial cell.

Fig. 2 shows a large installation for the city of Curacoa, D. W. I., for their municipal water supply. It has a capacity 20,000 gallons per 24 hours, and is a 12-effect apparatus, producing more than 7 lbs. of distillate per pound of live steam entering the initial cell.

During a recent drought this machine not only supplied the needs of the city where it was installed, but was operated at 100 per cent. overload, supplying the additional drinking water for several nearby towns.

The Properties of Saturated and Superheated Ammonia Vapor

A very useful and interesting paper of 94 pages with the above title has been published as University of Illinois Bulletin, Vol. X, No. 18 (University of Illinois, Engineering Experiment Station, Urbana, Ill.), the authors being Professor G. A. Goodenough and Mr. Wm. Earl Mosher.

The vapor of anhydrous ammonia first became of interest in the field of mechanical engineering with the advent of Carré's absorption and Linde's compression refrigerating machines. With the development and increased application of the refrigeration industry this vapor has become more important and an accurate knowledge of its properties is highly desirable.

The investigation of Professor Goodenough and Mr. Mosher was undertaken with the object of collecting and correlating the various scattered experimental data on the subject of the properties of ammonia and an attempt made to reconcile these data by means of well-known thermodynamic laws and prin-

ciples so that the results may be consistent with each other; and to express the various properties by means of formulas from which tables and charts in English units could be prepared for use in solving the many problems connected with refrigeration work.

The chief results of the investigation are given in form of four tables on twenty-seven pages.

Of the four tables given, the first and second are for the liquid and the saturated vapor of ammonia and give explicitly all of the properties that are ordinarily needed for use. Table 3 is primarily for superheated ammonia vapor, but includes the saturated vapor as the special case of zero superheat. Table 4 gives the thermal properties of liquid ammonia.

In tables 1 and 4 the argument is the temperature. In tables 2 and 3 the argument is the pressure.

Then follows a chapter on the Mollier diagram for ammonia.

In order to facilitate the solution of refrigeration problems, a heat content-entropy diagram was prepared which accompanies this bulletin. This diagram has two families of curves: (a) curves of constant pressure, and (b) curves of constant quality in the saturated region and constant temperature in the region of superheat. The ordinates are heat contents; the abscissas are entropies.

The tables given in the paper are based upon the most reliable experimental data available at the present time. In the final chapter this body of data is presented together with the derivation therefrom of the formulas from which the tables were calculated.

Anyone interested in refrigeration problems should acquaint himself with this excellent and useful work.

Personal

Mr. Courtland F. Carrier, Jr., who has been chemical director of the Vulcan Detinning Co. for the past four years, has severed his connection with that company and removed to St. Louis, Mo., where he is taking up a general consulting chemical engineering practice with Mr. James C. Lawrence of Memphis, Tenn., under the name of Lawrence & Carrier, Inc.

The Dorr Cyanide Machinery Co. has opened a New York office at 50 Church Street, to take care of its expanding business in metallurgical work and industrial lines. The office will be in charge of Mr. H. N. Spicer, one of the company's engineers. Mr. Dorr also will spend a large part of his time in the East, devoting himself to the company's business and professional work.

Mr. W. H. Gibb, for five years Pittsburgh representative of the Brown Instrument Co., was made general manager of sales of the Stupakoff Laboratories of Pittsburgh, Pa.

Mr. W. Goward, emeritus professor of metallurgy in the Royal School of Mines, London, will publish a treatise on the metallurgy of the non-ferrous metals.

Mr. Simon Guggenheim has been elected chairman of the boards of the several Guggenheim corporations, American Smelting & Refining Company, American Smelters Securities Company, and Guggenheim Exploration Company.

Mr. Franklin Guiterman has returned to New York from one of his periodical visits to the Colorado offices of the American Smelting & Refining Company.

Messrs. Charles Hayden, D. C. Jackling and C. M. MacNeil have completed a tour of the western zinc and copper properties under their control, and have gone to Alaska to inspect their gold mining interests.

Mr. Julius Marcus, until recently chemist with the Ray Consolidated Copper Company, Arizona, has accepted a position with the Braden company in Chile.

Mr. Seabury C. Mastick announces that he has admitted Mr. Henry J. Lucke into partnership under the firm name of Mastick & Lucke, attorneys and counselors at law, 2 Rector street, New York City. Mr. Lucke is a graduate of Johns

Hopkins University, was for two years an instructor of chemistry, physics, and mathematics at Lafayette College and for seven years and a half was an assistant examiner in the U. S. Patent Office, serving in the division of electrochemistry and metallurgy and electricity, and for the past five years was practising law in New York City.

Mr. J. B. Shatzer, Pittsburgh representative of the Schutte & Koerting Co., will give a "Safety First" lecture on automatic engine stops and triple service valves before the National Association of Stationary Engineers in Pittsburgh on November 17.

Mr. F. W. Skirrow, chemical engineer, has accepted a position on the teaching staff of the University of Colorado, at Boulder, and will give lectures in industrial chemistry, at the same time remaining open to engagement in a consulting capacity.

Mr. E. J. Wagor has been superintendent of the melting and refining departments of the United States mint at San Francisco.

Mr. F. L. Zimmerman has been appointed Eastern representative of the Hoskins Manufacturing Company, of Detroit, makers of electric furnaces, pyrometers and heating appliances, to succeed Mr. E. L. Smalley. His headquarters are at 30 Church Street, New York City.

Notes

The Colorado Chapter of the A. I. M. E. has been organized with the following officers: Wm. J. Cox, chairman; C. J. Moore, vice-chairman; C. L. Colburn, secretary-treasurer; T. B. Stearns and Richard A. Parker, members of the executive committee with the officers. The chapter has jurisdiction in the state of Colorado.

The Abbe Engineering Company, of 230 Broadway, New York, announces that they have purchased the Sellman Mill Company and the pulverizing and grinding machinery business of G. M. Ball & Son, together with all the patents, drawings, patterns, good will, etc., of the foregoing concerns so that they are in a position to supply new mills, also repairs and supplies for the machines bought of these concerns. Mr. Henry Sellman, who has been building pebble mills and installing complete grinding plants for the past thirty-four years, is now with the Abbe Engineering Company in their engineering department. The Abbe Engineering Company state that they now control over thirty patents on various kinds of pulverizing and grinding machines.

High-Voltage Testing Transformers and Complete Testing sets is the title of Bulletin 570 of the American Transformer Company, of Newark, N. J. Two standard equipments are described, one for 50,000 and the other for 5,000 volts.

Electroplating with Trisalyt, the useful little pamphlet of the Roessler & Hasslacher Chemical Company, 100 William St., New York City, on the use of trisalyt (a metallic triple salt for electroplating copper, brass, bronze, zinc, gold and silver) has now appeared in the fourth edition. An interesting new edition is a formula for salt water gilding.

Irrigation is the title of a very neat and beautifully illustrated pamphlet of the Henry R. Worthington Hydraulic Works, 115 Broadway, New York City, on the conservation and distribution of water for irrigation, with many technical details of pumping machinery and tables of useful information on irrigation work.

The Log-Book of the Tower Plant is the title of an illustrated circular of the Yarnall-Waring Co., Chestnut Hill, Philadelphia, Pa., on the construction and uses of the Lea V-notch recording liquid meter. This liquid flow meter was described in our October issue, 1911, (Vol. IX, pp. 557), and also was the subject of an elaborate paper by Mr. D. Robert Yarnall before the annual meeting 1912 of the American Society of Mechanical Engineers. This paper has also been reprinted by the Yarnall-Waring Co. in pamphlet form.

Interesting Photographs from the Field is the title of a little and very neat booklet published by the Hardinge Conical

Mill Company, 50 Church Street, New York City, showing rather interesting photographs of some large mill operations in this country, as well as some typical Hardinge mill installations.

Pure Iron versus Copper-Bearing Steel is the title of Bulletin 5 of the Institute of Industrial Research, of Washington, D. C. The sub-title of this pamphlet of 47 pages describes it as "a brief for the plaintiff with historical data bearing upon the development of rust-resisting metals in the United States." The author is Dr. Allerton S. Cushman. In conclusion "the writer can only express the hope that those engineers and others who are accustomed to purchase material under carefully drawn specifications will not be influenced by a movement which proposes to overcome the bad effects produced by the usual impurities in steel by the simple expedient of adding another one (copper). The modern tendency throughout the whole great field of industrial development is towards a higher purity of product. The development of a pure iron as a commercial possibility is in line with this general progressive movement. It would be regrettable if this evolution in the iron industry should be retarded or halted by this retrogressive propaganda in favor of a special type of extra impure steel. It should always be remembered that the best is rarely the cheapest or the easiest to produce in any line of industry."

Tungsten Ore in Burma.—According to a consular report, wolframite has been discovered in the Tavoy and Mergui districts and a large number of concessions are being worked. The greater part of the output comes from float deposits and the ore is concentrated by the natives with pan, sluice-box and rocker. The average concentrates contain about 65 per cent WO₃. The cost of recovery and transportation to England is about \$315 per ton; but with ore selling at \$7 to \$8 per unit a good profit remains.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

REFINING METALS (Continued).

533,596, dated Feb. 5, 1895, Henry A. House, of Bridgeport, Conn., assignor of one-half to Robert Rintoul Symon, of London, England.

Relates to apparatus for refining metals, particularly silver, by electrolysis. In a suitable tank or vat is a horizontal shaft, with means for rotating the same, and on said shaft I mount one or more cathodes and one or more anodes of the impure metal to be refined. The cathodes upon which the metal is deposited are in the form of segments of a disk carried by an insulating support and adapted to be alternately connected with the circuit while in the solution and cut out of circuit during that part of their movement when they are out of solution. The anodes of impure metal are also carried by suitable supports, and may be cast in the form of annular disks or in segments that are secured to such support and similarly arranged to be brought into and cut out of the circuit. Under each rotating electrode is a removable canvas bag to catch the impurities or particles of metal that fall from the electrodes, and under all the electrodes and bags a still larger removable bag. Above the level of the solution are brushes that sweep over the surface of the anodes for removing bubbles of gas and impurities that collect thereon; and scrapers that bear on and remove from the cathodes the film of deposited metal and cause it to drop into a suitable trough. When the electrodes are rotated, current passes from each anode segment through the solution to the opposite cathode segment, the electrode segments out of the solution being cut out of circuit. By the use of a proper solution and current density, the silver is deposited on the cathode segments in a loose, spongy state from which it may be scraped by scrapers into the troughs or bags beneath.

545,328, Aug. 27, 1895, William H. Wiggim, of Worcester, Mass.

Relates to a process and apparatus for refining metals, etc., by electrolysis. The apparatus consists of a series of tanks having guides attached to the inner sides for holding electrodes in a vertical position. Above the tanks is a shaft on which are a plurality of cams, and levers pivoted on supports and their free ends resting on the cams. At an intermediate point, the levers support the electrodes in the tanks. The rotation of the cams oscillates the levers, which in turn impart a sudden shaking movement to the electrodes, removing any accumulated gas bubbles or impurities adhering thereto. The impure metal plates are electrolyzed as secondary electrodes, the electrolyte maintained in circulation by feeding it in at one end and withdrawing it at the other end. The patent contains a reference to patent 467,484.

546,364, Sept. 17, 1895, Donato Tommasi, of Paris, France.

Relates to the refining of metals by electrolysis. The apparatus consists of stationary anodes of the metal to be refined and a rotary cathode, the latter consists of a radial frame mounted upon a shaft, and adapted to receive sectors of conducting material, such as metal, or an agglomerate of carbon and copper oxide, the latter being reduced by the hydrogen, thereby reducing polarization. The rotating cathode sectors are so connected electrically that only the submerged parts are connected, the exposed parts absorbing oxygen from the air and in turn serving to reduce polarization. Scrapers remove the deposited metal as the cathode leaves the solution; the mechanical rubbing also reducing polarization. When metals are to be plated from solutions, anodes consisting of spongy or reduced metal, such as copper, lead, etc., whose oxide is insoluble in the electrolyte, are used; these take up the oxygen, and are later electrolytically reduced in a separate cell. The apparatus and process may be used for refining and obtaining copper, lead, zinc, nickel, silver, tin, argentiferous slags, matte, speiss, ores, etc., also obtaining the silver from Pattinsonized lead or skimmings, etc., appropriate electrolytes being used.

566,673, Aug. 25, 1896, Charles W. Fielding, of London, England, and Louis B. Walker, of Elizabeth, N. J.

Relates to electrolytic refining of metals, using secondary electrodes; the anodes to be either of cast or rolled metal; and attached cathodes of metal or material either similar or dissimilar to the metal in the anode, but preferably made of a paste spread over one side of the anode and allowed to harden before use. The several compound plates are separated by spherical insulators suspended on a cord or other carrier. The spheres touch in points only, and therefore permit the consumption of the entire anode.

569,722, Oct. 20, 1896, John T. Morrow, of Great Falls, Mont.

Relates to the refining of metals and is for a case or receptacle for containing the ends and scraps of anodes. The case may be made of metal less electropositive than the scrap copper in the electrolyte, in which case only the scrap copper will be anodically dissolved; or of non-conducting material and make contact with the scrap copper through a copper shoe resting upon the scrap which is replenished as fast as it dissolves.

570,133, Oct. 27, 1896, William DeCourcy May, of Niagara Falls, N. Y.

Relates to refining metals, and consists of a series of similarly shaped vertically nested pans, which may be made of the metal to be deposited, or of non-conducting material. Electrolyte is supplied to the top pan, and overflows to the one below at one side; from this pan it overflows to the next lower one from the opposite side, thereby circulating the electrolyte in each pan. From the bottom pan it overflows into a receptacle in which it may be purified before re-use. The anode consists of metallic shot or other fragments, which is placed within each pan, the cathode being the underneath submerged side of the pan above, the electrolyte in each pan rising above the level of the underside of the upper pan. When of non-conducting material, a conducting coating is applied as cathode, and suit-

able connection made from the coating to the copper shot within.

578,953, March 16, 1897, Frederic A. Thum, of Newark, N. J. Relates to an apparatus to be used in refining metals, which consists of a long oblong tank, which may also be annular, in which is placed the electrolyte and the cathodes. Suspended within the tank are smaller cells or carriages, supported by wheels running on a track without, and upon which the cell may reciprocate. The cell has a perforated bottom covered by a filter cloth, on which is placed the metal to be refined, either in a fragmentary condition, or otherwise. Anodes made of metal to be refined rest upon the fragments and make contact through a flexible wire and roller to a rail conductor. The cathode may be a plate in the bottom of the outer tank, or may consist of a number of removable pans in which the deposit is made. The reciprocation of the cell stirs the liquid and removes bubbles, etc. Anode slimes are retained on the filter cloth.

588,035, Aug. 10, 1897, William Thum, of Newark, N. J.

Relates to apparatus used in the refining of metals, which consists of a tank having a slanting bottom, with a trough at the lower end of the bottom. The cathode rests on the slanting bottom and projects into the trough. Anode cells similarly shaped, and lined with filter cloth, are slidably mounted in the tank, and have a perforated slanting bottom parallel to that of the tank. The metal to be refined is placed, in a fragmentary state, in the anode cell, contact being made through a removable casting of the metal placed thereupon. Within the trough at the bottom of the tank is placed a removable receptacle of porcelain, etc., into which the deposited metal is pushed periodically. A similar trough and receptacle are in the anode cell, to collect the slimes. The liquid is suitably circulated by an injector, or by compressed air.

588,524, Aug. 17, 1897, Edward Balbach, Jr., of Newark, N. J.

Relates to apparatus for refining silver and other metals, which consists of a tank of earthenware, etc., having a bottom partly flat and the remainder inclined, the entire bottom preferably covered with carbon plates or other conductor. Within this tank are removable skeleton frames which have grated bottoms; the frames contain removable anode compartments having filter-cloth bottoms. Upon the filter cloths are placed the bars of metal to be refined, to which contact is made by removable castings of the metal electrically connected to the positive pole. The deposited metal collects as crystals, etc., and is periodically removed by a scraper. The anode slimes remain upon the filter cloth.

Book Reviews

Metallurgy. By Cecil H. Desch. Second edition; small octavo (18 x 11.5 cm.); 411 pages, 14 plates, 108 diagrams. Price \$3.00 net. New York and London: Longmans, Green & Co.

For this new edition additions have been made to bring the work up to date, while the chapters on the physical properties of alloys and on the metallography of iron and steel have been practically rewritten. The method of handling the subject matter and the author's style are considerably better than in the first edition (which itself, however, was well done), so that this new edition may be unreservedly recommended as a clear, systematic and skilful presentation of the subject.

Liquid Steel: Its Manufacture and Cost. By David Carnegie, assisted by S. C. Gladwyn. Octavo (14 x 23½ cm.), 520 pages, 10 plates and 252 illustrations. Price 25 shillings; in New York \$7.50. London and New York: Longmans, Green and Co.

The author was formerly a Sheffield steel maker, and is now steel works consultant and engineer; his assistant is a consulting engineer. Their chief aim is to compare systematically the costs of all the steel-making processes, giving details of composition and cost of raw materials, construction and ar-

angement and cost of furnaces and plant, and tabulation of labor costs and cost of living in different countries.

The work, however, contains more than this; it gives incidentally a larger amount of information about the processes themselves, and the principles upon which they are based and worked, given in a clear and succinct manner.

The antiquated £. s. d. make the reading and comparison of costs very unsatisfactory to anyone but a Britisher; but we feel thankful for cwt. and quarters having been replaced by tons and pounds. The illustrations, plates, paper, type and binding are all satisfactory. The book will prove valuable to a large circle of technologists.

The following figures and conclusions from the work may interest others than mere technologists: They give in relative figures the wages received for the same kind of labor, the expense for the same kind of living, and the relative state of "affluence" of the workingman, in the countries named, taking England in each case as the standard:

	Germany	England	America
Wages received	75	100	200
Cost of living	120	100	150
"Coefficient of comfort"	62.5	100	133

In brief, the German workman is on an average 37½ per cent. worse off and the American 33 per cent. better off than the English; or the American may be said to be 113 per cent. better off than the German. These figures are strictly true only of the iron and steel industry, but they agree fairly well with the reviewer's observations and conclusions in other industries; they therefore approximate to being true in general.

* * *

A New Era in Chemistry. Some of the most important developments in general chemistry during the last quarter of a century. By Harry C. Jones. 326 pages. Price \$2.00 net. New York: D. Van Nostrand Company.

"Although the development of chemistry has taken place more or less by leaps and bounds, it is difficult to fix an exact date as the beginning of the 'New Era.' The year 1887 marks the appearance of the first volume of the *Zeitschrift für Physikalische Chemie*, and in this volume the epoch-making papers by Van't Hoff, on the Relations between Solutions and Gases, and of Arrhenius on the Theory of Electrolytic Dissociation appeared. This date, 1887, is, therefore, taken as the beginning of the New Era, which is, then, a quarter of a century old.

"It is, however, clearly recognized that there is a difference between the chemistry of twenty-five years ago and that of to-day. That this is really a difference in kind is not always clearly understood, either by those who have watched the development during that period or by those who have not studied chemistry long enough to have the necessary perspective.

"It has seemed desirable to point out as clearly as possible in what this difference consists; how these new developments were brought about and by whom. This is the object of this little work."

There are twelve chapters dealing with the conditions of chemistry in 1887; development of the law of mass action; the energy changes that take place in chemical reactions; Van't Hoff, Le Bel and Guye and the origin of stereochemistry; the phase rule of Willard Gibbs; chemical dynamics of Van't Hoff and chemical and chemical equilibrium of LeChatelier; the rôle of osmotic pressure in the analogy between solutions and gases; Arrhenius and the theory of electrolytic dissociation; the saltate theory of solution and the importance of solutions for science in general; the work of Wilhelm Ostwald in inaugurating the new era in chemistry; investigations by the students and coworkers of Wilhelm Ostwald; the electron and radiochemistry.

This book is testimony of a sympathetic nature and its charm rests to a large extent in the author's personal reminiscences of Van't Hoff, Arrhenius and Ostwald. The title of the book is undoubtedly too broad for its contents, but those phases of the new era of chemistry which are connected with these three men are covered with genuine enthusiasm.

Metallurgical and Chemical Engineering

A Consolidation of *ELECTROCHEMICAL AND METALLURGICAL INDUSTRY* and *IRON AND STEEL MAGAZINE*.

Organized Research in America

In his brilliant recent presidential address before the American Chemical Society, Mr. Arthur D. Little remarked pointedly that while "Germany has long been recognized as pre-eminently the country of organized research," yet its pre-eminence in industrial research is now being threatened by a new competitor, which is "strangely enough the United States—that prodigal among nations still justly stigmatized as the most wasteful, careless and improvident of all." While most of the industrial effort in this country still proceeds under the guidance of empiricism with a happy disregard of basic principles, yet many of our manufacturers have already learned that "efficiency of production is a sounder basis for prosperity than mere volume of product, however great" and that the most profitable output of their plant is "that resulting from the catalysis of raw materials by brains." Catalysis of raw materials by brains—this is industrial research.

Mr. Little's record of what industrial research in America has so far accomplished is a long and noble list of achievements, which promises much for the future. But what we want to comment on especially in this note is not so much what has been achieved as how it has been achieved—or as it has been sometimes put, though erroneously, "the question of individuality versus organization."

Most of the early achievements must be credited straight to the genius of strong individualities of superman size. Edison is a typical example. And that the Edison spirit is not yet dead, that specialized intense research is still being carried out by independent individualities and can be carried out with success, Dr. Backeland has proved more than once. But it is true that under the new, more complicated social and industrial conditions of modern times most of the problems inviting research now require the facilities and resources of large corporations, and that organized research is replacing independent research.

Though this is perfectly true, it would be folly to imagine that organization can ever replace individuality. Research can be organized, but it will always require individualities of the most pronounced character. At this place last month we paid a tribute to the latest great achievement of the Research Laboratory of the General Electric Company—the two-candle per watt lamp. In Mr. Little's address we find an interesting account of how work is carried on at that laboratory. Dr. Whitney is quoted as follows: "We see a field where it seems as though experimental work ought to put us ahead. We believe that we need to get into the water to learn to swim, so we go in. We start back at the academic end as far as possible, and count on knowing what to do with what we find when we find it. Suppose that we surmise that, in general, combustible insulation material could be improved upon. We try to get some work started on an artificial mica. Maybe we try to synthesize

it and soon come to a purely theoretical question; e.g., is it possible to crystallize such stuff under pressure in equilibrium with vapor corresponding to the composition of real mica? This may lead a long way and call in a lot of pure chemistry and physical chemistry. Usually we just keep at it so that if you haven't seen it in the market we're probably at it yet." Clearly work of this kind requires strong individualities, but the work of the different research men is held together by their organization under a leading master spirit and by a mutual exchange of ideas between all at weekly colloquies.

Now the problem looms large: What can the Government, represented by the Government bureaus, do to help industrial research in this country? A broad, positive answer is difficult. But this much can be said that being a government of the people and by the people it should never undertake anything that would bring it into competition with individuals or classes of the people. The scope that remains is large. The Reichsanstalt in Germany has shown how to do it; so has the Bureau of Standards in Washington, which was justly congratulated at the last iron and steel meeting of the American Institute of Mining Engineers on its excellent research on the critical ranges A₂ and A₃ of pure iron. The problem is a peculiarly trying one for the new Bureau of Mines, but this Bureau is to be congratulated at least on its willingness to confer concerning the organization of its research work with the representative national scientific and engineering societies.

Competition Among Metallurgical Processes

Progress is rapid and change is frequent in the metallurgical industry. Just as one branch of ore treatment seems to have reached the limit of its efficiency, and the demand seems imminent for a radical change in methods, ideas are evolved that give the older methods a new lease of life and defer the possibility of success of the new proposals. We have in mind particularly the situation in regard to complex base-metal ores, and the relative possibilities of mechanical concentration, hydrometallurgy, and electrometallurgy in their treatment.

Advocates of each type of process are enthusiastic and optimistic as to the advantages of their respective favorites. Perhaps concentration is on the defensive; for the admitted limitations of physical processes have acted as a spur to the hydrometallurgist and electrometallurgist. At the same time, the deficiency of mechanical concentration, fully recognized by the loyal experts in that field, has forced them to perfect and adopt improvements that will strengthen their position against their possible competitors. And so the competition grows keener and keener, to the ultimate benefit of the industry.

There are several matters in this number of the journal that will afford food for reflection to all, and some degree of encouragement to each of these factions. The discussion on the present position and future prospects of zinc metallurgy at the recent joint meeting of the New York sections of the American Electrochemical Society and the American Institute of Mining Engineers, reported in full in this issue, is interesting in this respect, though the general discussion was rather tame compared with the discussion on the same

subject at the last Denver meeting of the American Electrochemical Society. While the remarkable advances made in the concentration of complex zinc ores in recent years were not touched upon in the meeting at New York, yet the relative present position of the retort process, the electric-furnace process, and the electrolytic process came out very clearly, as well as the position of some of the chief representatives in the different camps, optimists and pessimists and agnostics.

Of great encouragement to the ore-dressing fraternity will be the note of improvement in dry concentration and separation, as recorded in this issue in the description and work of the Plumb pneumatic jig. It suggests possibilities that ought to be interesting to those who are not now getting satisfactory returns from their labors. It emphasizes the enhanced value of high-grade as compared with low-grade concentrates, and the necessity of working to meet the smelter's demands.

Imperfections reside in all of our processes, but the different types merit consideration. Their ultimate success or failure will be determined by the net profit resulting from their application. In this regard, a discussion started on another page, for and against a hydrometallurgical scheme, should serve a useful purpose. Several other communications referring to the same subject came too late to be printed in this issue and have been held over for the January issue. It is better to bring ideas to a focus in print than to talk aimlessly and in generalities. As suggested in the discussion, if concentration is to hold its own it must awake to the possibilities of improvement, and reduce the tremendous losses entailed in poorly separated products; and the goal of competitive metallurgical processes must be a cost of production so low that it can not be ignored.

The Modern Blast Furnace Burden

According to the official statistics the manufacture of 29,726,937 gross tons of pig iron in 1912 involved the consumption of about 55,656,000 gross tons of domestic and foreign iron ore, ore briquets, etc., and about 4,319,000 tons of mill cinder, scale, scrap, slag, zinc residuum, etc. As the latter item is only about one-thirteenth the former it does no great violence to add the two together, and compute that the average furnace burden was equivalent to 2.017 tons of ore per ton of pig iron manufactured, making a yield of a shade under 50 per cent. Without undertaking to go into details as to the loss of metallic iron in slag, flue dust, etc., it is evident that the average iron content of the ores used was less than 50 per cent, since the average pig iron contains only about 95 per cent iron.

Between 80 and 85 per cent of all the pig iron of the United States is made from Lake Superior ores, while the imported ores are of relatively high grade, leaving it that the comparatively low-grade ores used by Southern furnaces do not operate greatly to pull down the average yield. The showing is much less favorable than would have been made, say, fifteen years ago, when the cream of the Lake Superior deposits was being used. Unfortunately there are no statistics for such years, but it is readily recalled that ores running well above 60 per cent were the rule rather than the exception.

The ores have been changing and the conditions of operation change with them. The pig-iron producer adapts himself to the changes without inconvenience. The difference in conditions appears on the surface not in the form of its having become more difficult to operate a blast furnace, but from its being impossible to produce pig iron as cheaply as formerly. More ore must be mined and transported, and more fuel and flux must be consumed, simply adding to the expense.

It should be noted that the gradual exhaustion of the Lake Superior deposits which were first selected for exploitation does not always lead to the mining of a lower-grade ore. There are three factors, the iron content, the character of the impurities, and the cost of mining. In the early days of the Mesabi range, when ore was literally "as cheap as dirt"—certainly if one undertook to place orders for "dirt" in hundred-thousand-ton units he would find it rather expensive—if a 60 per cent ore lay in 100-ft. thickness on the surface and a 65 per cent ore of the same thickness lay under 100 ft. of overburden the former would have been mined and the latter left as impractical at the time, but today conditions would be different. Very good ores are now being mined, at great outlay of capital in removing great overburdens, and thus the exhaustion of the earlier mined deposits leads in one direction to the mining of lower-grade ores, but in another direction to the mining of deposits which are very good, but expensive to get at.

The ease with which pig iron is made with a much more expensive burden than that of fifteen years ago suggests how easy it will be to continue using lower and lower grade ores. We shall make tens of millions of tons of pig iron, perhaps nearly a hundred million tons, for every unit that the average ore used loses in iron content, and in making that pig iron we shall obtain ample experience to attack the new problems successfully. Inasmuch as the visible supply of iron ore increases very rapidly for each notch that the limit of commercial availability is dropped it is clear that iron for future generations can readily be found. A higher price, measured by unit of endeavor, will have to be paid, but through the endeavor being better directed the cost will not be enhanced in proportion. If the cost should advance when measured by dollars per ton, the public will undoubtedly have a correspondingly increased ability to pay. The consuming public can now pay the average price of \$14 a ton which pig iron now commands much more easily than it could pay the \$9 to \$10 per ton which pig iron made from Lake Superior ores brought at its historic low point, late in the nineties, when very rich ores were being used.

An Old, Old Question Considered Prismatically and an Humanistic Hortation

Let us take a ray of sunlight and pass it through a prism. We all know what happens. The white light is decomposed into its optical components and we have the spectrum of red, orange, yellow, green, indigo, blue, and violet. What was a co-ordinate entity has been resolved into several entities and each not separate but blending into its neighbors.

Now compare the flux of social thought, which is made of many divers hues to a decomposed ray of light. We have two extreme classes of thinkers, one whose stomachs

are full and whose souls are self-sufficient, and who quack solemnly "whatever is, is right" and we have another class of iconoclasts with lean and hungry looks, who say "whatever is, is wrong." Between these two opposed classes, we have those of lofty cosmocentric souls, who chant "whatever is true, must be right, let us advance slowly and surely onward and upward to the right." These classes grade into each other in many ways for the individual himself will be a conservative in one subject and a progressive in another subject. A man will yell "halt" and try to sit on the tail of progress in metallurgy while he will be a contributor to the funds of the Socialist party. We see that it takes all sorts of people to make up this round world.

Now all these discordant anthropological elements in the eyes of the Great Intelligence make up a white sunbeam of spiritual light. We should, therefore, be not too impatient with the "standpatter" if we have radical views on a question, nor damn with faint praise the efforts of the sane upbuilder if we are recognized by ourselves and by others as authorities on any subject. For physics teaches that a ray of light to be pure white must have many seemingly diverse elements.

Now physics teaches also that outside the visible spectrum, there is the invisible. Thus we have the infra-red which gives heat without light and the ultra-violet that gives light, could our purblind eyes detect it. So too, in politics and technology we have the commonplace reactionary who fires away, sputters and gives no real light on the points at issue and the far-sighted visionary who throws his rays into the projective and transcendental future and is described as a wild-eyed crank by those round about him.

But between our physical vision and our psychological vision there is this important difference. What colors our eyes can distinguish to-day we will see as the same to-morrow, next day, and forever. But what we see mentally as truth and reality does not necessarily see the same to-morrow or next day, for we are being swept along in the great flow of thought and as the world moves, we nolens, volens must move with it. So what once was thought as unbelievable becomes belief, and the agnostic gets to know the unknown and sees the invisible.

This age is an intensely practical age. Such is a plain fact, but it is likewise a plain fact that this age is an intensively theoretical age. Most of the foregoing has been speculatively and theoretically considered. Now we will ask the reader to look at the question in a humanistic and direct-acting way, in a manner and in a way that will affect his own life. Which should a person be—a wise, cheerful, sane optimist or a crabbed, aged pessimist?

Now the sane optimist subdues his pessimism and uses it to cheer his spirit. He knows full well the motto "nisi parer, imperat."

Which should a right-thinking person be? Might he not consider this: "Between the optimist and the pessimist the difference sure is droll, the optimist sees the doughnut and the pessimist sees the hole." We may add that the calm, self-contained optimist usually eats the doughnut as soon as he can see it. And the traditional food of New England is more substantial than the circumspect hole or the circumambient air. The community of pessimist-subduing, early-rising optimists is a good society to join.

Readers' Views and Comments

Reduction of Blue Powder

To the Editor of Metallurgical and Chemical Engineering:

Sir: My attention has been called to an error appearing in my article in your November issue, page 637, in which I state, "Moreover, Dr. Haanel has informed me that he has melted tons of blue powder, after mixing it with carbon in proper form and amount." Although I believed I was stating a correct impression received in conversation, it now appears that the statement is unqualifiedly wrong, and I wish to make a complete retraction to relieve Dr. Haanel from any wrong implication.

We had agreed that the excessive production of blue powder was not necessarily objectionable if it could be cheaply converted into spelter. Probably it was in this connection that I misunderstood Dr. Haanel's remark.

Electric Tin Smelting

To the Editor of Metallurgical and Chemical Engineering:

Sir:—On page 593 of your October issue an article is referred to under the heading "Electric Tin Smelting," given by "A Special Correspondent" in the *South African Mining Journal*, June 7 and 14, 1913.

On reading this through I find that practically all the information given therein is identical with the data and conclusion given in my article, "Electric Tin Smelting," published in your journal, Vol. IX, No. 9, page 453, September, 1911, although no reference to that article is made in the review.

Luton, Beds, England.

Annual Tables of Physical and Chemical Constants

To the Editor of Metallurgical and Chemical Engineering:

Sir:—I desire to make public acknowledgment of contributions made this month toward the expenses of publishing the "Annual Tables of Physical and Chemical Constants": New Jersey Zinc Company, \$50; International Acheson Graphite Company, \$25; Castner Electrolytic Alkali Company, \$25; Mathieson Alkali Company, \$25.

Lehigh University.

JOS. W. RICHARDS.

Induction Furnace Notes

To the Editor of Metallurgical and Chemical Engineering.

Sir:—In my article on the above subject, published in the October issue of your journal, a few minor errors occurred, which I now wish to correct.

(1) As to the thermal efficiency (page 561) an error appeared in the formula given. It should read

$$E = \frac{350,000}{804 \times 606} = 67.1 \text{ per cent, not } 63.8 \text{ per cent.}$$

(2) The cooling water was found to be just under 1.4 gal. per min. or round 50,000 gal. for 160 tons of steel. As the cost of the water from the mains used is 6d. per 1000 gal. This works out to a little under 2d. per ton of steel.

(3) The tilting arrangement is not used to any extent at present, as it was found that the use of a sound taphole was more beneficial to the lining generally, and also probably to the quality of the ingots.

(4) The tar-magnesite lining has again been abandoned. The first mentioned method of lining has been taken into regular use, though with a few technical alterations, the nature of which is not divulged for publication. When the men got thoroughly used to its behavior, cracks in the lining are now a very rare occurrence and need not be feared.

(5) The labor casts have been revised and are slightly higher than given in my schedule; in addition, two "shank men" at \$8 are employed per shift. The smelters receive about 98

each per shift, and the laborers' wages are also slightly higher. Against this stands the fact that the necessary margin for sundries has been materially lowered so that the total cost per ton remains pretty much the same as stated.

England.

JOH. HÄRDÉN.

Micrometry as Applied to Alloys

To the Editor of Metallurgical and Chemical Engineering:

Sir:—The review of the very interesting paper, "Micrometry as Applied to Alloys," by Dr. C. H. Mathewson, in your November issue, calls to my attention a method of measuring the areas of alloy constituents which I have used very successfully. It is a modification of Sauveur's polar planimeter method combining its accuracy with the shortness of the ruled square method.

Two ways of measuring areas with the planimeter are now in general use: (1) taking a photomicrograph of the alloy and measuring the areas from a print, and (2) projecting an image of the alloy on a screen and tracing the areas to be measured with a lead-pencil. The penciled areas are then measured with a planimeter.

I used a screen consisting of a piece of plate glass, $\frac{1}{4} \times 15 \times 15$ in., coated on one side about $1/32$ in. thick, with a mixture of paraffin and tallow. If now the coated glass be used with the waxed side up, in conjunction with a Bausch and Lomb photomicrographic camera, the areas can be traced in the wax with a planimeter according to Sauveur's method. The camera should be in a vertical position thus making the glass horizontal. It is best to confine the waxed portion of the glass to an area about 4 in. diam. In this way the fixed end of the planimeter can be so placed that the roller moves on the glass without danger of encountering the wax.

The wax used was obtained from candles and the amounts of paraffin and tallow were not determined. It is evident that an opaque wax is desirable since it permits the use of a thinner coating. If the coating is too thick and the areas to be measured are small, the tracing point of the planimeter has a tendency to break the wax when an area is about seven-eighths surrounded. In discussing this difficulty with Mr. F. A. Fahrenwald, 2168 Stearns Rd., Cleveland, O., he suggested mixing some white powder with paraffin to make it more opaque and thus permit the use of a thinner layer. Of several powders tried we found that starch was the best. The paraffin is first melted and then powdered starch added slowly with vigorous stirring, until the mixture is pasty. We found that glass coated with a layer of this material .008 in. thick would give a much better image than ground glass.

After a determination has been made the wax can be melted by applying the flame of an inverted bunsen burner, after which the plate is ready for another determination.

Electric Zinc Smelting

To the Editor of Metallurgical and Chemical Engineering:

Sir: Referring to the article on Electric-Zinc Smelting by Mr. Louvrier in your November number, will you kindly allow me space to disclaim the intention of imputing to him, in my paper of last August, the expression of the opinion that "the production of carbon dioxide in actual electric furnaces, was approximately equal to that formed in the Belgian retort."

On the contrary, I understood him to say that "the excessive production of blue powder in electric furnaces is due to the formation in the electric furnace of a much higher percentage of carbon dioxide than in the usual retort."

I expressed as my own opinion, that either he was mistaken in this opinion, or that the excess of oxygen came from another source; for the reaction $\text{ZnO} + \text{CO} = \text{Zn} + \text{CO}_2$ will give the same amount of CO_2 in either case.

I also ventured to express my opinion that the reaction $\text{CO}_2 + \text{C} = 2\text{CO}$ would be equally rapid in both cases.

I also stated that in my opinion, the electric current, by forming cavities in a paste, partly fused charge, might prevent the intimate contact required between the carbon dioxide formed and the hot carbon, in order that the second reaction could take place.

I offered as proof of this, that a rapid reduction of zinc could not take place unless the carbon dioxide was rapidly reduced, and suggested that some of the carbon dioxide escaping into the slag-lined passageways, might pass into the condenser without an intimate contact with carbon.

The amount of carbon dioxide formed being the same in both cases, the percentage of it which passes into the condenser in an electric furnace, may thus be much greater than in the Belgian retort. This may be the result either of a defective construction in the particular furnace under consideration, or of some inherent difficulty in reducing zinc at the temperature of an electric furnace.

At the time my article was written I had no idea that Mr. Louvrier had designed a zinc furnace, and, of course, had no idea of criticising it.

This is plainly a case of misunderstanding which should be avoided if possible, and I wish to dispel in the minds of Mr. Louvrier, and any of your readers, the thought that I have treated him unfairly.

F. L. CLERC.

Hydrometallurgy: Joys of Its Theory, Woes of Its Practice

To the Editor of Metallurgical & Chemical Engineering:

Sir: In reading Dr. Chauvenet's objections to "hydro schemes," in your September issue, I wondered why he selected for attack dry chlorination as typical of hydrometallurgical processes, for not a single "woe" that he gloats over applies to the method in its present development. He surely must have had in mind chloridization of a period much earlier than the "early attempt at Helena," or the developments at Corbin, Mont. As well take as an example of current cyanide practice, the process in its stage of development fifteen years ago, as to refer to chloridization today in terms of concentration roasting, sodium chloride electrolysis, ferric hydroxide precipitation, water washes, diluted solutions and fractional precipitation.

The prominence of dry chlorination as the most likely process in the field for the solution of the complex-ore problem is attested, not only by a score of engineers of unquestioned ability, but now by its unexpected selection as a typical example of "hydro schemes," with no specific "woe" charged against it.

If overcoming a simple problem of eliminating ferric hydroxide is to be termed "much ingenuity," "we" would bankrupt the English language in trying to express what has been done to overcome the *real* difficulties which have been encountered and successfully solved in the development of chloridization.

What engineer of real training and experience would offer as proof of the success of any hydrometallurgical process, the results of a test, whether on a gram, pound, ton or carload, if such test had not been made under commercial conditions of apparatus, reagents and time. Continuity of operation has no small bearing on the testing of a process. I do agree that engineers should know the relation of test work to actual practice. My experience has convinced me that the principal difference between a test on a few pounds and one on a ton (if both are intermittent) is the difference in the cost of making such tests.

Why eliminate as a class of material for wet treatment the available complex zinc ores which are not too low-grade, but rather too complex? I submit that in the consideration of

any scheme, its field of operation and the purpose for which it is being developed should determine largely its possibilities. In other words: Will we "get a run for our money?"

In the October issue of your journal, Mr. Bleeker defends in a general way hydrometallurgical possibilities, but he has touched upon chloridization under the so-called Malm process just enough to expose his ignorance of the subject by his reference to its theory and calcium sulphate.

I am interested in the development of chloridization solely from an established conviction that it offers the solution of the complex-ore problem. To this end I am prepared to defend it, and welcome any sincere, specific criticism devoid of repartee or hair-splitting. This will offer to Mr. Bleeker an opportunity to enlighten us further on "calcium sulphate in the Malm process," and I trust will make available these columns for a discussion of the relative merits of various proposed schemes of dry chlorination.

To establish my position, I state that my experience with chloridization has been through the gram to the ton test in as thorough an investigation as intermittent tests will permit, then to a test with commercial-size apparatus under conditions indicated by the work on a smaller scale. This latter installation was made at Corbin, Mont., and proved a failure under the methods which the preliminary tests indicated would work successfully. From this failure was evolved a method which of necessity discarded all specially constructed apparatus, and made use of standard apparatus excepting only the special construction of minor parts and the development of a simple, cheap, fool-proof electrolytic cell for the decomposition of zinc chloride.

This work covered a period of three years, during which time the weak points of the process became apparent and were overcome. The difficulties encountered were solved in such a way as to simplify the method, so that in its present development all of the "bugaboos" mentioned by Dr. Chauvenet (many of which never existed) have vanished into thin air.

I stand for a form of chloridization which, at least to myself, has proved a success in yielding a high recovery of gold, silver, copper, lead and zinc in metallic condition at a cost, under normal Colorado conditions, of 2½ cents per pound of metal recovered. In the last analysis the success of any commercial operation is determined by its net financial return.

I therefore have no proof of the success of chloridization. If there were the case the plant at Georgetown, Colo., would not be in its uncompleted state. It was to bring the process to a stage of commercial proof that the installation at Georgetown was undertaken. At present the plant is about two-thirds completed. It was designed on data obtained from the Corbin plant and from later special investigations, to treat all ores, whether sulphide, oxide or carbonate, but more particularly complex ores of gold, silver, copper, lead and zinc. The present installation bears evidence as to the comparative simplicity of apparatus and operation proposed.

During the eight years which I have given to this method of ore treatment, I have not encountered a difficulty which has not been readily solved, and no difficulty is foreseen which is any greater than those which are the regular diet of engineers who do things. Oh, yes, "the cost will finally prove its death." In that connection, let me state that the value of ores available will permit the cost to more than double and still show a substantial profit on ores which have no market value at present.

JOHN L. MALM.

Denver, Colo.

Great Falls Electrolytic Copper Refinery

To the Editor of Metallurgical and Chemical Engineering:

Sir:—The paper on the "Great Falls Electrolytic Plant," by Willis T. Burns, presented at the Montana meeting of the American Institute of Mining Engineers and published, slightly abstracted, in your September issue, has brought up some thoughts which I herewith offer.

Re Purification of Electrolyte by means of insoluble anodes, the writer states that using insoluble anodes with a speed of flow of electrolyte of 4 liters per minute four tanks removed 99.3 per cent of the arsenic, leaving the bismuth still in solution. In December, 1910, Harold Schroeder in the *Australian Mining Standard* published details of a similar method of purification of electrolyte conducted at Lithgow, N. S. W., in 1908.

The object he concisely states under "Scheme" as "to purify the liquor and at the same time produce the least possible quantity of impure copper." To effect this, as much pure copper as possible is deposited by sending the liquor through a cascade of tanks with insoluble anodes just sufficient to ensure the lowest one giving pure copper on last cathode. In this plant five tanks were used, for the double reason that that number necessitated no alteration in the ordinary flow arrangements and that it still left the ordinary number of insoluble-anode tanks in use for keeping the copper strength of all electrolyte on works at a constant figure. The outlet from the fifth tank was used to fill tanks in which the impure copper was to be made, no circulation of liquor taking place in those tanks beyond the ordinary air-lift circulation in each tank.

The figures published show a steady and regular daily deposit of the arsenic, but the bismuth was deposited much more rapidly than the arsenic. In fact where seven days were required to remove the bulk of the arsenic, the bismuth was all removed from solution in less than half that time. This is confirmed by the analysis of the deposits, these being divided into hard cathode, metallics and fines of the powdery part, the ratio of bismuth to arsenic always being higher in the metallic portion.

Having personally supervised the whole of this experimental purification, I may say that what suggested this method of cleaning electrolyte was largely, having noted on several occasions that when the circulation of liquor was accidentally stopped or slowed down during the night in the insoluble anode tanks, the tanks at the end of the cascade produced dirty copper, and sometimes a cathode had the top 6 inches black and the lower part clean bright copper. Samples of electrolyte from the tank containing such a cathode, drawn off in zones from top to bottom of tank, showed differences as to copper, arsenic and bismuth contents. To this H. Schroeder draws attention.

Our experience on the Australian works differs completely from that given in Mr. Burns' paper.

It would be of interest to know if the removal of the first of the copper by crystallization has been found more economical than the making of pure cathode copper till the solution reached the "danger point" for such.

Re the Treatment of the Slimes and Impure Copper Produced, it would also be of interest to know whether any other method than blast-furnace treatment has been tried; further, whether the anodes cast from converters at a time when much of this impure copper was coming around, carried a higher percentage of arsenic than the average anode. It is worthy of time to evolve a method of treatment by which a minimum of the arsenic would eventually return to the liquor, whether from blast-furnace matte or the after-treatment of flue dust from the roasters or converters that expelled it from the impure copper deposit.

In another part of the paper the writer states, "all of the silver present in the cathodes is deposited mechanically from the slimes in suspension." This I find very interesting as bearing out what I have always maintained, and we have proved conclusively at the works at Lithgow by the use of sand filters and by analysis of cathodes. Details are given in E. H. Blake-more's paper on "Electrolytic Refining," read before the Australian Institute of Mining Engineers, and published in its *Proceedings*, February, 1910.

It is to be regretted that the author of the paper on the Great Falls plant makes no comment on the use of chlorine in the electrolyte, which I see was kept at 0.40° grm. per liter.

* The figure should be 0.044. The figure in the September issue was a misprint. Editor.

In Lithgow we proved it to have a decidedly bad effect in relation to the gold and silver in the cathode copper.

Gourock, Scotland.

HARRY A. B. MOTHERWELL.

* * *

To the Editor of Metallurgical and Chemical Engineering:

Sir:—Replying to Mr. Harry A. B. Motherwell's comments above on my notes on the Great Falls Electrolytic Plant reprinted in your September issue I wish to say that the bismuth in the copper treated at Great Falls is present in very small quantities, as compared with the other impurities, and as it has shown no tendency to increase in the electrolyte its elimination has not been studied.

Since the receipt of Mr. Motherwell's comments a bismuth determination has been made on samples of the inlet and outlet solutions of a group of four insoluble anode tanks employed in purifying electrolyte. No bismuth was found in either sample. Had bismuth been present in these solutions it would probably have been deposited with the arsenic.

Regarding the economy of first removing the copper from the impure electrolyte, by crystallization, before treating in the insoluble anode tanks for the removal of impurities I may say that this method has been found much more economical than attempting to obtain commercially pure copper in insoluble anode tanks operated at 35 amperes per square foot when the electrolyte is circulated at a rate of speed sufficiently slow to insure the deposition of a large amount of arsenic. Even were it possible to recover most of the copper in this way we would find the scheme impracticable as our working electrolytes would become depleted in copper as the increase in copper contents of the electrolyte, per ton of copper refined, decreases as the current density increases.

Regarding the arsenic contents of anodes produced at the smelter while the arsenical slime from the insoluble anode tanks is being treated there, it may be said that no material increase in impurities in the anodes is noted.

The purpose of adding chlorine to the electrolyte is to precipitate antimony in the form of an oxychloride. We have observed no effect of the chlorine on the silver and gold contents of the cathodes.

W. T. BURNS.

Great Falls, Montana.

Conductivity of Fluosilicic Acid and Lead Fluosilicate

To the Editor of Metallurgical and Chemical Engineering:

Sir: As there is, to my knowledge, no published data on the conductivities of fluosilicic acid and lead fluosilicate, the constituents of the electrolyte used in electrolytic lead refining, I thought the following tables might be of interest.

These results were obtained in the Electrochemical Laboratories of the Pennsylvania State College. The method employed was that familiar to anyone who has worked with conductivities, namely, the one due to Kohlrausch, which is essentially the standard Wheatstone bridge method of resistance measurement, with the exception that an alternating current is substituted for a battery and a telephone receiver for a galvanometer. Before making any measurements the slide-wire bridge was calibrated by the method of Stronhal and Barus, and all subsequent readings on the bridge were corrected from the calibration curve obtained. Two conductivity cells, having platinized-platinum electrodes, were used, one cell having a high and the other a low "cell constant."

The acid used in making up the solutions was the pure concentrated fluosilicic acid, a clear syrupy liquid, bearing the following analysis:

N. V. M. = 0.005 per cent

SO₂ = 0.002 per cent

The salt used was the crystallized lead fluosilicate of the formula PbSiF₆ (4H₂O).

All results given in the tables are the means of at least three readings.

Table I gives the conductivity and equivalent conductivity of fluosilicic acid at 25 deg. C.

TABLE I

Conductivity and equivalent conductivity of fluosilicic acid at 25 deg. C.

Normality	Per cent of acid in solution	Conductivity in reciprocal ohms per centimeter cubed	Equivalent conductivity

N/64 "	0.0076	0.0254	0.00838	0.00362
N/128 "	0.0076		0.00702	0.00265
N/256 "			0.00772	0.00224
N/512 "			0.00750	0.00200
N/1024 "			0.00750	
No salt	0.0070	0.0250	0.00708	0.00102

Table II gives the temperature coefficient of the conductivity of normal fluosilicic acid (corresponding to 7.2 per cent free acid) from 20 to 45 deg. C.

Table III gives the temperature coefficient of the conductivity of 1/16 normal fluosilicic acid (corresponding to 0.45 per cent free acid) from 20 to 45 deg. C.

Table IV is a conductivity table of various mixtures of fluosilicic acid and lead fluosilicate at 25 deg. C.

When the results obtained in Table IV are plotted, as in Figs. 1 and 2, they show, at a glance, the great effect that the free acid has in increasing the conductivity of the electrolyte.

Niagara Falls, N. Y.

T. ARTHUR PATTERSON.

The Continuous Sand Plant in Cyanide Practice on the Rand

To the Editor of Metallurgical and Chemical Engineering:

Sir:—In your issue of July 1913 appears an article by Mr. H. N. Spicer in regard to Rand methods, and under the heading "Cone Classification of Sand and Slime" Mr. Spicer refers to rotary vacuum filter tables of local invention in use at the City & Suburban G. M. Co., and alleges certain disadvantages in connection with the use of these tables.

The tables referred to, and also the special type of cone used in conjunction with same, are the invention of Dr. W. A. Caldecott, and the method of handling sand by means of table and cone in the manner described is known as the "Caldecott continuous sand plant," and as the writer has had a great deal to do with the installation of these plants, as Dr. Caldecott's representative, he would like to comment upon Mr. Spicer's article. The alleged disadvantage, as stated, are based on faulty premises.

Loss of Head.—Mr. Spicer seemingly overlooks the fact 85 per cent of the total weight of pulp, in the shape of slime and water, overflows the diaphragm cones, and return-sand cones above the filter table, and the total loss of head of this amount of pulp is only about 2 ft., which can hardly be considered a serious matter. The remaining 15 per cent of the pulp is the only part which has any considerable loss of head, as it is this amount of the total pulp which is delivered as a thick candy pulp from the underflow of cones on to the sand filter table.

These percentages are based on ordinary Rand conditions of 5½ parts water to one of solids in the pulp from the mill, and with cone underflow containing not more than 30 per cent of moisture. The sand delivered by underflow of cone amounts to 50 per cent of the original solids; the other 50 per cent being slime which overflows cones.

The disinclination to any loss of head requiring elevation and return of a portion of the pulp in a reduction works, whatever advantages may be derived therefrom, and however advantageous it may be found elsewhere, is quite a marked feature of the older American and Mexican ore-treatment practice, and is, apparently, due to the fact that, in the early days, the side of the hill was always selected as the site for the reduction plant, and full advantage was invariably taken of the use of gravity for transferring pulp from one stage of treatment to another, and any departure from the gravity system has been adopted very slowly and cautiously, but in the more modern American and Mexican plants there is a growing tendency to the use of circuits in milling, especially in tube milling and the use of a circuit necessarily means the re-elevation of some part of the pulp. In connection with this matter the article by Herbert Lang in the July 5 number of the *Minning & Scientific Press*, page 7 is of interest as showing the trend of modern metallurgical practice.

In regard to the double treatment mentioned by Mr. Spicer, I presume he refers to the use of return sand cones, but, as stated above, the use of these cones only involves the loss of about 2 ft. of head on 85 per cent of the total pulp.

Sand Filter Tables.—The cost of operating Caldecott Tables at the City & Suburban G. M. Co., referred to in Mr. Spicer's article, expressed in American currency, is as follows:

	Per Ton of Sand:	Per Ton of Ore:
Power	2.36 Cents.	1.31 Cents.
Maintenance	0.43 "	0.23 "
Labor	0.58 "	0.33 "
Totals	3.37 Cents.	1.87 Cents.

The value of the original sand is 3.52-dwt., and the value of the residue is 0.371-dwt.

It will be seen from the above figures that the metallurgical efficiency of the system is high, and that the cost of power and maintenance is very small, which is due, principally, to the fact that the table revolves at a very slow speed, viz.: one revolution in 3 minutes. In regard to the cleaning of filter cloths, this work is performed in half-an-hour by two natives.

Necessity for Two Tables.—While in all continuous operations it is desirable to be able to cut out a unit periodically still it has been found possible, on the Princess Estate & G. M. Co., to work with one filter table and yet obtain most satisfactory results under proper supervision as can be seen by reference to Mr. H. A. White's contribution to the discussion on the Metallurgy of the Homestake Ore, which appears on p. 55 of *Bulletin No. 100* of the Institution of Mining & Metallurgy.

In Mr. White's article he shows that the sand residue at the Princess Estate, over a period of three months, had an average value of 0.23-dwt., so it can be seen that the use of one table only gave excellent results. Mr. White's article also shows the extremely low value of last drainage solution of 0.05-dwt., and this is due to the fact that, by the Caldecott system, the slime is completely eliminated, resulting in very clean sand.

At the Princess Estate the sand treatment is what is termed "single" treatment, i. e., the extraction of gold from the sand is completed in the vat into which the sand is transferred from the filter table, and the residues are so low that they would not pay for transferring into another vat for the purposes of being given a further treatment.

The advantages claimed for the Caldecott patent continuous sand plant are as follows:

- I. Efficient classification of sand and slime in tailing pulp.
- II. High percentage of slime which can be treated by cyanide at less cost than sand.
- III. Clean, leachable sand charges, permitting free aeration, and facilitating the dissolving of gold, and the washing out of gold with decreased volume of solution.
- IV. Clean sand residue, for sand filling.
- V. Low cost of plant operation and maintenance.
- VI. Lower capital expenditure for plant.
- VII. Dissolving of gold in sand by cyanide solution begins within half-an-hour of ore being crushed in battery.
- VIII. Less volume of gold-bearing solution to precipitate.

The validity of the foregoing claims is evidenced by the fact that at present about 20 per cent of the total Rand tonnage is being treated by this process, and the following is a list of companies using the Caldecott process, together with the respective ore tonnages treated *per month*.

	Tons
(a) Simmer & Jack Proprietary Mines, Ltd.,	70,700
(b) Jupiter G. M. Co., Ltd.,	42,400
(c) Simmer Deep, Ltd.,	63,000
(d) Princess Estate & G. M. Co., Ltd.,	22,800
(e) Geduld Proprietary Mines, Ltd.,	24,000
(f) East Rand Proprietary Mines, Ltd.,	170,000
(g) New Klemfontein G. M. Co., Ltd.,	45,000
(h) City & Suburban G. M. Co., Ltd.,	27,500
Total	474,400

Crushing in Water.—Mr. Spicer writes as though there is nothing in favor of the Rand practice of crushing in water, and while impartial judges readily admit the desirability of crushing ore in cyanide solution where the percentage of recovery by amalgamation is trivial—as in connection with gold telluride, or silver sulphide ores—still, they are equally ready to admit the fallacy of crushing in cyanide solution where a high percentage of the gold can be recovered by amalgamation.

It is certainly unsound, metallurgically, to crush Rand ore in cyanide solution and thus needlessly incur trouble from corroded copper-plates, liability of loss of gold-bearing solution, base bullion due to deposition of dissolved copper and zinc, and the more prolonged and expensive cyanide treatment necessitated by richer tailings. Further, crushing in cyanide solution renders it impossible to obtain accurate screen values, due to the presence of dissolved gold in solution.

The crushing of Rand ore in cyanide solution has been tried on a large scale, and abandoned for the reason stated above, and as a great deal of expense was incurred in converting mills to make them suitable for crushing in cyanide solution, there was, of course, every inducement not to revert to crushing in water, but the troubles experienced were so great that such a change was found to be absolutely necessary.

In America you have the Homestake Co., treating an ore of about the same characteristics as regards amalgamation as Rand ore, and it is interesting to note that the Homestake crushes in water.

Rand Metallurgists are becoming rather used to outside criticism, and an article appearing in the August 9th, 1913 issue of the *South African Mining Journal*, under the heading "Rand Metallurgical Methods," would doubtless interest some of your readers. It reads as follows:

"In two or three recent issues of this journal we have printed extracts from overseas critics of Rand mining and metallurgical methods. The views of gentlemen like Mr. Motherwell, of Australia, and Mr. Spicer, of America, the two other large gold producing continents of the world, have, we understand, attracted much local attention, and it is generally felt that their comments on Rand metallurgical methods are scarcely just.

"Briefly stated, most of these overseas critics, while applauding the general organization and magnitude of operations on the Witwatersrand, find fault with the metallurgical practice of the Main Reef series. One or two of them attack the methods pursued in mills and cyanide works on the ground that they are antiquated and conservative. Other technical visitors who have recorded their impressions appear to find fault with Witwatersrand metallurgists in that they have borrowed ideas from all other mining countries.

"On the face of it these statements seem contradictory to one another. If the argument that our equipments and devices are obsolete is tenable, then the view that the Rand is to be condemned because our technical experts have not been slow to appreciate the value of the ideas of other mining camps cannot very well be supported, for it obviously infers a denial of the first-named statement.

"The essential view which most of these critics seem to lose sight of is that the primary object of mining is the earning of profits for shareholders. The enunciation of this basic economic fact leads one on to a consideration of a number of logical corollaries. In the first place it should be recognised that progress in ore treatment means making more profits from the same grade of ore. It may or may not, however, involve (a) new processes or devices—a 'different' method or device is not necessarily a 'better' one; (b) a reduction in working cost; (c) higher percentage recovery.

"Critics who have machinery or processes to exploit consider that the employment of a new device or a new method is synonymous with progress. Often they do not take best results but those which favor their own purposes. Progress may involve the use of new devices or the employment of new methods, or it may consist in (a) better use of existing appliances; (b) economy through better arrangement of known devices; or (c) better organization of work.

"On the Rand all types of practice are represented, from those of the pre-war epoch to those of 1913, but no individual existing plant represents all known 'best' practice. During the last few years there has been a large accumulation of knowledge requiring to be digested and profitably applied. Local conditions make many devices and methods unsuitable here, as for instance, the large scale of operations precludes the 'small

handy machine,' of limited capacity, just as a 3s. per day Kaffer may be more economic than a mechanical device with an 8s. per day white man.

"Another important consideration is that many devices have been tried locally and have been found wanting, which are claimed to work well elsewhere. The results of the successes only are made public; experience with failures is generally kept quiet for obvious reasons. Then, too, it must not be overlooked that the low average grade of ore and large sums of capital in plants and interests involved on the Rand preclude rash changes being recommended by those who are trustees for shareholders, and gambling merely in the name of progress with shareholders' money is a breach of faith.

"Notwithstanding all this, it must be admitted by all unprejudiced critics that Rand practice is good. At present Rantek is treated with a total residue at 0.3 dwt. at a total cost from shaft to dump of 3s. 2d. per ton. In fact, Rand practice of today represents combined efforts of many able men from every part of the world for a quarter of a century; the combined result of large capital and experimental expenditure. It is essentially a process of evolution and survival of the fittest. Note, too, that there is very little scrapped machinery, representing waste of shareholders' money on these fields.

"Gradual development has usually admitted of utilization of existing plant combined with its extension on more modern lines.

"Another important aspect of progress is this: At any time and on any mine there is an 'economic limit' of extraction or residue beyond which it does not pay to go, since such extra gold costs more than it is worth. Other essential facts to remember are the simple nature of the Rand ore which does not require many appliances in use elsewhere. The large scale of operations makes organization of great importance, and the group system with specialist staff at the disposal of each mine gives these mines advantages single companies cannot afford.

"To sum up, we believe that in crushing practice, in stamp and tube milling and classification with limited supply of water the Rand is ahead of the rest of the world. When an appliance from abroad (e. g., tube mill) which is suited for use here arrives it is promptly adopted and fully utilized. There are probably more tube mills in use on the Rand today than anywhere else in the world."

It occurred to me the article quoted may interest your readers as representing the Rand side of the question.

EDW. L. BATEMAN

Johannesburg, South Africa.

The Western Metallurgical Field National Radium Institute

For over a decade the carnotite deposits of southwestern Colorado and southeastern Utah have been exploited in a desultory way. They have been regarded mainly as possible sources of vanadium and uranium, and up to two or three years ago the ores were mined and treated for those metals exclusively. Recently, however, a new phase has been put on the whole situation by the general recognition of these ores as a source of radium; and the demand for salts of the latter element has lent an added value to the deposits. Not only has this district come into prominence in the eyes of American scientists, but it has gained a world wide reputation, so that foreign capital has sought to purchase the ores mined there, or failing in that, to buy mining claims.

The vast change in the situation has been caused by a realization of the radium value of these ores; and with that realization came the feeling on the part of some of our altruistic scientists that this important resource should be conserved for the benefit of our own country; that the radium-bearing ores should be treated here instead of in Europe, and the radium placed at the disposal of American scientists. The result is the organization of the National Radium Institute, directed by Dr. James Douglas, of Phelps Dodge & Co., New York; Dr. Howard A. Kelley, of Johns Hopkins University, Baltimore.

Dr. C. F. Burnam, associate of Dr. Kelley; Mr. Archibald Douglas, nephew of James Douglas, and Mr. E. J. Maloney, of Wilmington, Del. The institute has provided capital for the purchase of carnotite claims, and the mining and treatment of the ore. A cooperative agreement exists between the institute and the national Bureau of Mines, whereby the latter carries on the technologic study of the ore treatment and supervises for a time the actual process of recovering the three valuable constituents, uranium, vanadium and radium. The institute is a philanthropic body to the extent that its capital is to be expended in the production of radium which will not be sold, but used for scientific purposes.

The radium value of American uranium ores can be best comprehended from the following facts: In 1912 the United States produced 28.8 tons of U_3O_8 , equivalent to 24.4 tons of metallic uranium. All but a few tons of this was shipped abroad. On the basis of the normal equilibrium between radium and uranium, this production represented 9.77 grams of radium chloride or 12.7 grams anhydrous radium bromide. But on the basis that the ratio of radium to uranium in carnotite is about 10 per cent below the equilibrium value, the above uranium production in 1912 contained radium equivalent to 8.8 grams radium chloride or 11.43 grams radium bromide. Contrasted with these figures we have the fact that the Austrian production of radium chloride in 1912 was only 2.23 grams. In making this comparison it must be remembered that the figures from Austria represent radium chloride actually produced, while those for the United States give only the radium content of ore shipped from the country; but allowing a recovery of 85 per cent of the radium in the United States ore, it is seen that our local production was still three times as great as that of Austria, the principal producer.

The reduction plant of the National Radium Institute will be built in Denver, where it can be under the immediate supervision of the officials of the Bureau of Mines who are charged with the technologic work on rare metals. The mill will be adapted to the application of several of the processes which have been evolved in the Bureau's Denver laboratory. None of the details will be made public until the results are officially announced through the Bureau.

With the impetus given to the radium industry by the organization of the institute, and the cooperation of the federal government, we may expect to witness a few disreputable promotions by unscrupulous parties who will prey on the public through promises of fabulous returns on a small investment. Such a development must result in inevitable loss to investors, besides reacting unfairly on a few commercial undertakings of a legitimate character. It would seem to be in order to sound a warning against promiscuous investment in "radium" companies.

Concentration in the Joplin District

Representatives of the Bureau of Mines have recently spent some time studying the methods of mining and concentrating zinc and lead ores in the Joplin district, Missouri. Their observations are contained in *Technical Paper 41*. Joplin concentrating mills have been the subject of much criticism, particularly in regard to their inefficiency in treating the finer portions of the pulp. The jig practice is regarded with more favor, and is generally conceded to give excellent results on the local ores. "In the concentration of the fine material the operators of this district have, until the last few years, been rather behind in their methods, but are beginning to realize the importance of saving the finer mineral particles formerly wasted in the discarded sands. There are still several mills in the district that have no concentrating tables or sand jigs, no attempt being made to avoid the losses mentioned." Even in those mills where tables are used, little care is exercised to get good classification.

The loss in concentrating lead ore is not as great as in the case of zinc. "The average recovery of blende from the ore in milling is about 60 to 65 per cent. When the heavy losses in smelting zinc ores are included, the total loss in the production of zinc from the ore in the mine up to the commercial

product, reaches nearly 50 per cent." Tests were made on the feed and tailings from different mills, with the following results: On ore from "sheet-ground" mines, rougher jig feed contained an average of 3.57 per cent zinc, and the tailings 1.36 per cent. From other than "sheet-ground" mines, rougher jig feed contained an average of 2.79 per cent zinc, and tailings 0.84 per cent. The average table feed in a number of mills was 5.28 per cent zinc, and tailings 1.57 per cent. The losses in different sizes of tailings are shown below:

	Dry weight grams	% of whole	Zinc assay %	Loss %
Oversize to $\frac{3}{8}$ in.	2426	15.225	0.77	12.256
$\frac{3}{8}$ in. to 3 mm.	7579	47.565	0.96	47.608
3 mm. to 1.5 mm.	3817	23.955	0.76	18.946
1.5 mm. to 0.46 mm.	1659	10.412	0.71	7.678
Undersize through 0.46 mm. ..	453	2.843	4.55	13.512

An excuse for the tendency to sacrifice efficiency for capacity in the Joplin mills and mines, is found in the system of royalties which are imposed on lessees and sub-lessees. Royalties to owners of the ground run from 10 to 15 per cent of the gross output of mineral, and this is sometimes increased by the practice of subleasing, to 20 or even 30 per cent. The system results in waste in both mining and milling.

Strike Situation in Michigan

The latest reports from the copper country of Michigan are to the effect that normal conditions are gradually returning. Some demonstration of violence is still made by the strikers, particularly toward men coming into the district in search of work. These violations of the strike injunction have caused the arrest of a large number of strikers. The mine managers have issued a statement through the Copper Country Commercial Club to the effect that striking miners will be allowed to return to work, provided they have not engaged in riots and disturbance. An 8-hour day is to be established for underground work by the first of the coming year. As a result of these overtures work is being resumed and production is increasing. The Calumet & Hecla is employing nearly its normal quota of labor, and shipments of rock to the mills are being made to the extent of 7,000 tons daily. No shortage of labor is anticipated, as many of the iron miners are now available following the closing of some of the iron mines for the winter.

Settling the Fume Question in California

A state investigation of the differences between California smelters and farmers is under way, in accordance with an act of the last legislature which provided an appropriation of \$5,000 for the use of a commission charged with the determination of damage by smelter fumes to stock and vegetation. This commission is composed of Dr. W. F. Snow, secretary of the state board of health, Dr. Charles Keane, state veterinarian, and Dr. J. A. Cook, commissioner of horticulture. The first work of the commission is being done in Shasta county, where a number of smelting plants have been closed.

Dr. J. A. Holmes, director of the Bureau of Mines, visited the affected districts in Shasta county on his recent return from Alaska. It is understood that he regards the situation as more hopeful of settlement than at any time past. General prosperity of the farmers in the smoke belt has diminished their antipathy toward the smelters, and complaints are fewer and less bitter.

Company Reports

Quarterly reports of the activities of the large copper companies for the third quarter of 1913 show no marked changes in conditions compared with the first half of the year. The Utah Copper Co. produced 23,884,467 lb. copper from 2,035,391 tons of ore averaging 1.2450 per cent copper at a cost of 9.68 cents per pound. Crediting the net miscellaneous earnings, the cost would be 8.187 cents. The low grade of the ore treated was responsible for the comparatively higher cost. Both the Magna and Arthur plants are in good condition, and handled an average of a little over 22,000 per day for the quarter.

The Ray Consolidated Copper Co. produced during the third quarter of this year 12,969,120 lb. copper from 575,190 tons of ore averaging 1.72 per cent copper. The average mill recovery was lower and the operating cost higher than for the previous quarter, owing to shortage of water during the summer months, and to some important improvements in the mill. The average cost of copper produced, after allowing for smelter deductions and applying the earnings of the Ray & Gila Valley R. R., was 10.155 cents per lb.

The Chino Copper Co. produced 15,187,003 lb. copper during July, August and September, 1913. The total amount of ore treated was 507,650 dry tons, of an average grade of 2.23 per cent copper. The extraction averaged 66.98 per cent; the average grade of concentrate produced was 14.46 per cent copper. The cost per pound of copper, after allowing for smelter deductions, but without crediting miscellaneous income, was 8.41 cents. If miscellaneous earnings are credited, the cost is only 8.08 cents.

The Nevada Consolidated Copper Company's operations the third quarter of the year resulted in the production of 15,835,563 lb. of copper. The amount of ore treated was 813,153 tons, 93 per cent of which was from the pits and 7 per cent from underground workings. The grade of the ore was 1.53 per cent copper, which is lower than that for last quarter. The cost per pound of copper produced was 10.09 cents, which is much higher than that for the preceding quarter, viz., 8.95 cents. The grade of concentrate produced is decreasing on account of the character of the ore now being milled. Experiments are being carried on looking to a cheaper and better method of treating the low-grade slimes which are produced in milling, and which reduce the grade of concentrate.

The annual report of **Camp Bird, Ltd.**, for the fiscal year ended June 30, 1913, shows that the mine at Ouray, Col., is able to supply ore for only 25 out of the 60 stamps. The gross amount of ore treated was 30,012 dry tons. The content of the ore treated averaged as follows: Gold, 0.958 oz. per ton; silver 3.83 oz. per ton; lead, 1.42 per cent; copper 0.21 per cent. The saving of the gold amounted to 93.79 per cent. Of the total value extracted, there was obtained by amalgamation 49.28 per cent; by concentration 43.91 per cent; and by cyanidation 6.81 per cent. In addition to the above tonnage of ore treated, the cyanide plant handled also 1745 tons of impounded tailing, from which it is estimated that \$4,937 was recovered.

The Camp Bird company's operations at the Santa Gertrudis property in Pachuca, Mex., resulted in bringing up the capacity of the new mill to 25,000 tons per month. During the fiscal year there were treated 263,554 dry tons of ore of an average value of \$13.08 per ton. The recovery amounted to \$11.70 per ton, or 89.41 per cent. The old Guadalupe mill was not run during the year; but 761 flasks, or 28.6 tons of quicksilver were recovered from the old patio, yielding a net profit of \$17,335.

The Non-Ferrous Metal Market

Dullness has characterized the non-ferrous metal market during the period since our last report. Most of the prices have suffered a decline, and in cases where business has been good, the competition has been keen and prices have suffered. The dullness in some metal industries in this country, and the weakness of the London standard metal market have both been reflected in the domestic market.

Copper.—This market has been decidedly weak, and competition for orders has been keen. This has resulted in open cutting of prices, until unusual concessions were made. Business in Lake copper has fallen off until quotations are strictly nominal at 16@17 cents. Electrolytic is quoted at 15.25@15.30 cents.

Tin.—Prices have declined in the face of a fair statistical position of this metal. Considerable business has been transacted in a retail way, but the general tone of the market has not been strong. November tin in the domestic market is quoted at 39½ cents.

Lead.—This market has been fairly active, with sellers competing for such business as is in sight. The last available quotations are 4.15@4.20 cents, St. Louis, and 4.30@4.32 cents, New York.

Spelter.—This market has declined during the month. Business has been light and producers have made concessions to get orders from consumers. The last quotations are 5.05@5.10 cents, St. Louis, and 5.30@5.35 cents, New York.

Other Metals.—The aluminium market has shown dullness and little business has been transacted. The New York price for No. 1 ingots is 19¼@19¼ cents. Prices for antimony range from 6.50 to 7.75 cents for various brands, with a fair business in sight. The quicksilver market is steady with no material change in prices. New York quotes \$38.50 per flask of 75 lb. The domestic price at San Francisco is the same as for New York, with special prices for export trade.

The Iron and Steel Market

November has been a month of falling prices and sharply decreasing productions, the flow of orders having undergone a great diminution.

At the close of October the steel finishing mills were operating at an average rate of 80 per cent of full capacity; at the close of November operations were at an average of not more than 60 per cent, and prospects were that the rate would drop to 50 per cent before the end of December.

The report of a month ago suggested that enough had been developed to indicate that the tariff of October 4, 1913, was not directly the chief influence in the price decline. It is now clearly established that the tariff has had practically nothing to do with iron and steel prices, which have been falling because there was insufficient demand and therefore sharp competition for orders. It may be that the tariff is in part responsible for the general slowing down in business which has extended to steel, but that is really an altogether different factor.

The iron and steel market is passing through one of its periodic liquidations, and the nature and extent of such movements is well understood. The readjustment starts by orders becoming less than shipments, until eventually the mills must seek new business in order to maintain full operation. This results in price cutting and the open market declines. The existing contracts are on a basis below the open market, and when the market declines to or below the level of a given contract the buyer refuses to take any more deliveries under it without a price readjustment. This forces the mills to seek more new tonnage and then, unless there is artificial control of prices, the market declines rapidly. In the whole history of the American steel trade there is no case on record of prices being artificially maintained for the entire time from one period of activity to another. What has occurred at times has been the artificial maintenance of prices for a period, during which contracts would thus be kept alive and mills would be content to operate upon such business as was afforded at the controlled price level.

The most variable element in these periodic liquidations and readjustments is the time element. In that which followed the panic of October, 1907, the period of controlled prices lasted about 15 months, the actual liquidation and readjustment occurring during a few months following. The next time, in 1910-11, the period of control was less clearly separated from the period of active readjustment, the one merging into the other.

The present readjustment is sharply distinguished from its predecessors by there being no artificial control. The market is proceeding to the inevitable low point, not far from the cost of production, with relative rapidity. According to theories formerly promulgated in the trade, the element of time rather than of price reduction is the controlling one in forcing a revival in demand, but those theories have fewer adherents than formerly. If such a theory is correct, the price decline will not soon be followed by recovery, with forward buying and advancing prices, but there are many who urge that the

governing element is not time, but price, and that if a low point is quickly reached, the recovery will be correspondingly early. An excellent opportunity is about to be afforded to test the validity of the latter theory.

The total decline in finished steel prices now averages about \$4 per net ton, from the high point of last winter and early spring. The decline thus far represents about 60 per cent of the advance which had occurred from the previous low point, which fell late in 1911 and was the lowest average level in the finished steel market since 1898, when prices reflected the condition of there having been an industrial depression of five years' duration, with wages and supplies very low.

Pig Iron.

Although pig iron experienced an extensive decline during the first seven months of the year, the decline proved insufficient to meet present conditions, and the recovery which began in August came to an end about the middle of October, since when the market has been falling rather rapidly. During the first seven months of the year the average decline was about \$3 per ton, while August and September showed an average advance of 30 to 35 cents. Since the middle of October there has been a further decline of nearly 75 cents, so that the market is now about \$3.35 a ton below the level at the beginning of the year, which was substantially the top level in the advancing movement of 1912.

The pig iron market is almost absolutely stagnant as to inquiries and orders, representing stagnation rather than a normal dullness. In the summer there was a moderate volume of forward buying, due to the temporary stiffening in the market, and as deliveries are still coming in, and no forward buying is contemplated, orders and inquiries are far below normal at the moment. The actual consumption appears to be fairly large, although there has undoubtedly been some decrease. The current market stands as follows, with most of the quoted prices representing the ordinary asking figure and being susceptible of shading in the event of interesting orders being negotiated: No. 2 foundry, f.o.b., Birmingham, \$10.50; No. 2X, delivered, Philadelphia, \$15.50; No. 2X, f.o.b. Buffalo furnaces, \$13.50; No. 2 foundry, delivered, Cleveland, \$14.25; No. 2 foundry, f.o.b. Chicago furnaces \$14.75; at valley furnaces (90 cents higher delivered Pittsburgh) Bessemer, \$15.00; basic, \$13.00; No. 2 foundry, \$13.50; gray forge, \$13.25; malleable, \$13.75. Ferromanganese is \$50 for English and \$49.50 for German, f.o.b. Baltimore.

Steel.

As was the case in October, the unfinished steel market has been made not by important transactions in the open market, but by the readjustment of contract prices, agreed to by the sellers rather than allow the consumers to make inquiry in the market. On this basis we quote the market roundly at \$20.50 for billets, \$21.50 for sheet bars and \$26 for rods, f.o.b. maker's mill, Pittsburgh or Youngstown.

Finished Steel.

Since last report bars, plates, shapes and sheets have declined from \$1 to \$2 a ton. Nearly all products are weak, and present quoted prices represent what would be done on ordinary small lots, while in the case of attractive orders the prices would probably be shaded quite materially. Quotations are f.o.b. Pittsburgh unless otherwise stated:

Plates, tank quality—1.25 cents.
Shades, 1.30 cents.
Steel bars, 1.25 cents, base.
Iron bars, 1.45 cents, Pittsburgh; delivered Philadelphia, 1.27 1/2 cents; f.o.b. Chicago, 1.15 cents.
Wire nails, \$1.60, base; plain wire, 1.30 cents, base.
Sheets, blue annealed, 10 gage, 1.50 cents; black, 28 gage, 1.95 cents; galvanized, 28 gage, 2.95 cents; painted corrugated, 28 gage, 2.15 cents; galvanized corrugated, 28 gage, 3.00 cents.
Merchant steel pipe, 3 1/2 to 3 in., 80 per cent off list.
Steel boiler tubes, 3 1/2 to 1 1/2 in., 60 per cent off list.

Standard railroad spikes, 1.35 cents, Pittsburgh; 1.60 cents, Chicago.

Button head structural rivets, 1.85 cents.

Cone head boiler rivets, 1.95 cents.

Cold roller shafting, 62 per cent off list.

Carborundum Litigation

The United States Supreme Court has denied the application of the Carborundum Company for a writ of a *certiorari* in the case of the Electric Smelting & Aluminum Company versus the Carborundum Company, which had been formerly decided in favor of the former company by the United States Circuit Court of Appeals for the Third Circuit. This decision was given in some detail in our issue of April, 1913, page 203. This terminates this patent law suit of many, many years.

Refractories Manufacturers' Association

The recent Philadelphia meeting of the Refractories Manufacturers' Association was a very enthusiastic affair and well attended, considering the fact that all the members had to come from a considerable distance.

This Association is doing great work in the matter of standardization. Heretofore, the brick made was almost any size that the manufacturer wanted to make them. Now all the forty-five concerns which belong to the Association, manufacture the same sizes, both in silica and clay.

Colonel H. D. Savage, of the Ashland Fire Brick Company, of Ashland, Ky., is the president of the Association; Mr. J. E. Lewis, of the Harbison-Walker Refractories Company, of Pittsburgh, Pa., is the vice-president; Mr. J. H. Cavender, of the American Refractories Co., of Chicago, is secretary-treasurer.

The executive committee consists of Mr. J. L. Green, of the Laclede-Christy Clay Products Company, of St. Louis, Mo.; Mr. C. S. Reed, of the Chicago Retort & Fire Brick Company, Chicago, Ill.; Mr. E. S. Hitchens, of the General Refractories Company, Olive Hill, Ky.; Mr. D. D. Davis, of the Davis Fire Brick Company, Oak Hill, Ohio; Mr. T. E. Thomas, of the Niles Fire Brick Company, Niles, Ohio; Mr. J. H. McFeely, of the McFeely Brick Company, Pittsburgh, Pa.; Mr. George H. Diack, of the Queens Run Fire Brick Company, Lock Haven, Pa.; and Mr. C. H. Claiborne, of the Union Mining Company, Mt. Savage, Md.

The American Blower Company, of Detroit, Mich., have purchased the entire Air Washer interests, including patent rights, of the McCreery Engineering Company, formerly of Toledo, Ohio, and later of Detroit, Mich.

Gas Engines.—The Mesta Machine Company of Pittsburgh, Pa., has issued illustrated Bulletin 1 on "Mesta Gas Engines," built in sizes from 350 hp upwards for any class of service and for any fuel gas, such as producer gas, blast-furnace gas, coke-oven gas or natural gas.

Alunite has been discovered in Arizona and Nevada and the deposits have been investigated by the Geological Survey. No prediction of the value of the deposits is given, but they are considered as warranting further prospecting and development.

Electrolytic Coating of Iron and Steel with Lead.—The London *Electrician* of September 26 states that Lead, Ltd., has acquired a process devised by Mr. Sherard Cowper-Coles for the coating of iron and steel with lead electrolytically. It is stated that by this process lead can be economically deposited up to a thickness 1/8 in., and that the method is suitable for protecting iron and steel from corrosion, and for the lining of pipes, tubes and chemical vessels for containing corrosive liquids. Steel plates coated by this process are much smoother than the ordinary tinned plate, and there is no reduction in tensile strength or ductility. The process can also be used for the coating of earthenware and wood and for the protection of ornamental ironwork. The cost is stated to be low.

Present Status and Future Prospects of the Metallurgy of Zinc.

A symposium before the New York Sections of the American Electrochemical Society and the American Institute of Mining Engineers.

The joint meeting of the New York sections of the American Institute of Mining Engineers and of the American Electrochemical Society held on the evening of November 20 in the Engineering Building was well attended, there being some 200 members present, and the carefully arranged program deserved the interest which was shown.

There were three papers. Mr. George C. Stone presented a very careful review of the improvements which have been attained in the metallurgy of zinc with the time-honored retort process; Mr. W. R. Ingalls discussed the possibilities and limitations of electric zinc smelting, while Dr. J. W. Richards dealt with electrolytic zinc, having stepped in at the last minute to cover this phase of zinc electrometallurgy, as a promised paper by Dr. Victor Englehardt, of Germany, on this subject, had not arrived in time.

Mr. Lawrence Addicks, chairman of the New York Section of the American Electrochemical Society, presided during the presentation of the three papers. Mr. L. D. Hinton, chairman of the New York Section of the American Institute of Mining Engineers, presided during the discussion.

Improvements in the Retort Process

Mr. George C. Stone, of the New Jersey Zinc Company, in reviewing in a most interesting manner the development of the retort process, emphasized that while no spectacular or radical changes had been worked in the metallurgy of zinc as in the metallurgy of iron and copper by the introduction of converters, yet the progress had been as great with zinc as with the other common metals.

Three essential facts limit the possible apparatus for the production of zinc.

First, the temperature at which zinc is reduced by carbon is much above the volatilizing point of the metal, and it is, therefore, always produced as a vapor.

Second, to obtain a merchantable product the vapor must be condensed at a temperature well above the melting point of the metals. The temperature of the condenser must be close to the boiling point of zinc (920°) nearest to the retort and very much lower at the other end, because the condensation temperature depends on the concentration of zinc in the vapor and is lower the more dilute the vapor. The vapors are rich in zinc when they enter the retort and low in zinc when they leave it.

Third, the reaction by which zinc oxide and carbon monoxide are changed into metallic zinc and carbon dioxide is reversible. The reduction of zinc proceeds only until there is a certain ratio of carbon dioxide of zinc in the atmosphere and then stops, and in order to effect complete reduction there must be an excess of carbon always present.

These three essential facts control the type of apparatus to be used. It must be a closed chamber. It must be heated externally because the gas from the heating fuel must not come in contact with the charge. As the mixture of ore and coal forming the charge is a poor conductor of heat the size of the chamber containing it must be small in at least one direction or the heating will be too slow. The charge must, at all stages, contain a large excess of carbon to reduce at once all CO_2 formed. The condensers should be as close to the charge as possible and as small as will do the work in order to make it possible to maintain the proper heat gradient in them. The condensers must be kept within proper limits of temperature, diminishing towards the exit.

Mr. Stone explained in some detail why he questioned the statement commonly made that his spelter furnace is extravagant in heating, and then summed up the progress made in recent years as follows:

Forty or fifty years ago the typical Belgian furnace contained from fifty to ninety retorts of about 0.8 of a cubic ft.

capacity each. At the present time the furnace used in the natural gas field contain from 500 to 700 retorts of about 1.4 ft. each, an increase in capacity of about 1300 per cent. Furnaces containing 1008 retorts are in operation doing satisfactory work; this is an increase of about 2400 per cent in size and capacity. The increase in capacity of the spelter furnaces is, therefore, about the same as that of the modern coke furnace making pig-iron over the old charcoal furnaces.

More increase in size, however, does not amount to much unless accompanied by increased efficiency. In this respect the zinc furnaces show well. In the iron furnaces there has been no improvement in the proportion of metal recovered the old furnaces having given almost theoretical results. With zinc the improvement has been very marked. In 1844, at the Vieille Montagne works, the recovery was about 62 per cent, and even as late as 1880 a recovery of 75 per cent was considered good work. To-day 87 per cent is only fair, and many works can show runs of long periods averaging 90 per cent and over.

The fuel consumption has been decreased largely mainly by the adoption of regenerative gas-firing. Even in direct-fired furnaces the decrease is large. Comparing furnaces only using the same kind of coal, where the hand-fired furnaces twenty years ago required 3, $3\frac{1}{2}$ and even 4 tons of coal per ton of ore, well-equipped gas furnaces using the same coal, and working the same class of ore, now take only $1\frac{1}{2}$ to 184 tons.

Labor has also been largely reduced. The old Belgian furnaces required five days' labor per charge, two men working twenty-four hours continuously, and an extra helper on the day shift only. As these furnaces worked only about a ton of ore they required five days' labor per ton. At present all twenty-four-hour work is done away with, and not over 12 days' labor is required per ton.

In 1844 fifteen to twenty days was the usual life of a retort. Now good retorts made in hydraulic processes last from thirty to forty days, and at that more are replaced because they are filled up than because they leak.

Mr. Stone believed progress would continue to be made rather on the lines of improvement in the present retort process than by the adoption of radically different ones. He finally discussed briefly three different new types of processes which have been proposed, namely, the wet, electrolytic, and electro-thermic.

One main reason for the lack of success of the wet process is the difficulty of dissolving the zinc. Zinc blende usually contains a large amount of iron and when roasted the zinc and iron combine to form zinc ferrite, which is practically insoluble in either acids or alkalis under economic conditions. The purification of the solution is also expensive and rather troublesome.

Electrolytic zinc of excellent quality has been made by one firm for several years, but they have never increased the original plant. It is generally believed that this plant is only possible in connection with other operations carried on by them. Besides other difficulties of wet processes Mr. Stone said that electrolytic processes have the trouble of large power requirements.

Electric smelting of zinc ores is seriously limited in this country by the fact that in most mining districts electric power cost is high. Further, there are condensation troubles and other difficulties.

Mr. Stone concluded that the present types of furnaces can be much improved. Fuel can be saved by better design and proportions of regenerators; better arrangement of the ports and decreasing radiation losses by more thorough lagging of the parts of the furnaces from which radiation is purely wasteful. A determination of the best size and shape of retort and condenser for different ores, and the choice of such as suit the particular ore to be worked instead of using one size and arrangement for all, will give improved results in recovery and output. A careful study and application of the principles on which ores should be mixed offer a wide field for improvement.

Electric Zinc Smelting

Mr. W. R. Ingalls' discussion of the possibilities of the electric furnace for zinc smelting was very careful and conservative. Mr. Ingalls said he was neither a pessimist nor an optimist with respect to electric zinc smelting, but an agnostic. He agreed that electric zinc smelting was no longer in the laboratory stage and referred to some enlargements now being made in the electric zinc furnace plants of Norway. He thought reckless talk had held back the development of electric zinc smelting.

At considerable length Mr. Ingalls discussed the well-known condensation troubles, blue powder being obtained instead of spelter.

The fire-smelting process is a two-stage intermittent process of heating up and distillation. The electric smelting process is intended as one continuous operation. This distinction causes important differences.

The condensation troubles originate at least partly in the furnace itself. Mr. Ingalls distinguished between two kinds of blue powder—meltable and non-meltable. The fact that the condenser is too cold may account in part for meltable blue powder, while non-meltable blue powder is due to impurities in the vapor to be condensed—if it contains carbon dioxide, volatilized lead, dust and other impurities. Oxidized lead is often found in large extent in blue powder.

As to the different electric furnace designs for zinc smelting, Mr. Ingalls could not see any great difference between them. He thought there was not much in electric zinc smelting at present beyond visions and ideas. There were few figures and the subject was attracting attention chiefly on account of its mystery.

Mr. Ingalls then compared the different items of cost of electric smelting and retort smelting. But few of the items in question were known besides the cost of electric power as against coal. He thought the consumption of 1200 kw hours per ton of ore to be plausible though hardly yet an accomplished fact. As to the comparative cost of retorts and electrodes, he maintained his former statement that nobody can yet say which will be the weaker. If the cost sheet of the Trollhättan plant was refigured by inserting American for Scandinavian prices the cost of the application of the process would be found to be absolutely prohibitive.

Mr. Ingalls concluded that electric zinc smelting was still very much in its infancy and that at the present time all we could say was that we did not know.

Electrolytic Zinc

Dr. Joseph W. Richards then discussed electrolytic zinc. In order to show the variety of processes which have been devised in this field he gave a brief outline of the contents of Guenther's German book on the subject. He then took up recent developments with reference to a lecture by Dr. Victor Engelhardt which was published in abstract in our January issue, 1913 (Volume XI, page 43).

While Dr. Engelhardt considers the mere refining of commercial zinc analogous to copper refining, to be economically absurd, Dr. Richards thought it might be possible, under favorable conditions. It would, of course, be necessary to keep the solution clear. It can be kept free from iron by bubbling air through it, whereupon it should be filtered clear. Such an electrolytic refining process might be particularly advantageous if carried out for electroplating purposes.

Engelhardt had stated with regard to direct processes using soluble anodes containing zinc that many attempts had been made since 1880 to utilize the energy due to the solution of the anode and to prepare anodes containing various zinc compounds mixed with coke or coal powder with and without pressure with various binding materials, etc. All such processes have proven a failure. Dr. Richards thought, however, that packing the ore around an insoluble anode (instead of incorporating it in it) was a possibility. He then commented briefly on Engelhardt's description of the latest Siemens & Halske process with insoluble anodes and finally discussed broadly the scheme of sulphate roasting.

Dr. Richards thought that sulphate roasting was essentially a misconception. One gets a dilute solution of sulphuric acid which must be dispensed with after all the zinc is gotten out, and the sulphuric acid produced is a source of trouble.

The correct way to work is, according to Dr. Richards, to roast the ore to oxide as nearly as practical. It is then leached with sulphuric acid and electrolyzed in a double compartment electrolytic cell, zinc being deposited on the cathode and sulphuric acid is then used for leaching another quantity of roasted oxide ore whereby the acid is neutralized. The zinc sulphate thereby obtained is again electrolyzed, etc. In this process, therefore, the sulphuric acid passes continuously through this cycle. It is formed in the electrolysis, neutralized in leaching, again formed in electrolysis, etc. The first supply of sulphuric acid is obtained from the roast furnace gases. This principle is used in a plant at Butte, Montana.

Discussion

Dr. C. F. Chandler opened the discussion with a characteristic little speech. When the chairman, Mr. Huntoon, called him up Dr. Chandler said: "My old pupil gets even with me. He knows I am not prepared, and that is why he calls me up." He then spoke briefly on two occasions in his career when he got into connection with zinc—the first time, 50 years ago, in a poison-murder case, where he had trouble to get zinc free from arsenic, and the second time, later on, in a lawsuit on electrolytic zinc.

Mr. Woolsey McA. Johnson was then asked to give a review of his work on electric zinc smelting at Hartford, Conn. With respect to Mr. Ingalls' statement that a power consumption of 1200 kw hours per ton of ore was plausible and pretty good, Mr. Johnson said this would not be the minimum, but rather the maximum consumption he would consider acceptable. With a small furnace running with 25 per cent efficiency he had usually an energy consumption of 1400 kw hours per ton of charge, but he had also done it at 900 or 1000 kw hours. With a larger furnace he was sure to get a much higher efficiency and reduce the energy consumption correspondingly.

As to the electrode consumption this was $6\frac{1}{2}$ to 7 pounds of electrode carbon per 1000 kw hours, and he figured the cost of electrodes was considerably less than the corresponding expense for zinc retorts.

Mr. Johnson thought that the field of the electric furnace was not so much for plain zinc ores as for complex sulphide ores and by-product recovery must be considered if we want to see what electric zinc smelting can do and will do.

About roasting, Mr. Ingalls had expressed the opinion that the cost would be about the same for electric smelting and for the retort process. But Mr. Johnson pointed out that with the electric furnace it is by no means necessary to dead-roast the ore. Roasting down to 4 per cent of sulphur is about right for the electric zinc furnace. Sometimes in the Hartford plant they add green ore to get a matte. They do not want it to be too metallic and, therefore, add sulphur. This point should make a big difference in the cost of roasting for electric smelting and retort smelting. There is a vast metallurgical difference between a roast to half of 1 per cent and a roast to 4 or 6 per cent, both with respect to capital cost of the roasting furnace and with respect to the cost of roasting. Nine-tenths of all roasting troubles is caused by removing the last 40 or 50 lbs. of sulphur. This point also has a distinct bearing on the sulphuric acid plant for the reason that a richer gas is made. Mr. Johnson said that they are now building a three-ton furnace at Hartford, and he would be glad to show it to visitors. "Zinc comes from Missouri, and you have to show people."

Mr. Alfred H. Cowles spoke of some experiments made by him many years ago on electrolytic zinc. One difficulty which he encountered was the high resistance of the zinc sulphate solution; this was overcome by putting the electrodes close together by the use of two drums. The zinc deposited on the wires could be easily scraped off. The process used was cyclic with respect to sulphuric acid as described in Dr. Richards' paper.

The chief difficulty which was encountered was the melting

together of the finely divided zinc deposit. They tried for half a year all kinds of fluxes, but were unsuccessful until they found that it could be quite easily done with zinc chloride. It would be worth while to try this in the blue powder difficulty. The use of zinc chloride is not patented. Mr. Cowles pointed out that in comparison with aluminium production about one-seventh of the amount of energy is required to deposit a pound of zinc as is necessary to deposit a pound of aluminium.

Mr. H. A. Wentworth asked whether any unmeltable blue powder was formed at the higher temperature before the fumes reached the condenser at all. Mr. Ingalls said that he had no evidence to that effect and thought that the blue powder was formed in the condenser.

Dr. J. W. Richards referred to Mr. Ingalls' statement that there was no great difference between different electric zinc furnaces. While this might appear to be so at first glance, Dr. Richards insisted that there was a very great and important difference if the matter was investigated more in detail and the differences in the furnace designs had a great deal to do with the condensation problem. In the DeLaval type of furnace the fumes acted as resistor, and were thereby overheated, which increased the condensation difficulties considerably. On the other hand, a furnace using a buried arc or smothered arc was better, but it had zones of high temperature, and within these zones there was liability of evaporation of materials like silica or silicon which would later cause condensation troubles. But, in the whole, this type of furnace had certain advantages over the type in which the fumes acted as resistor. Finally, in resistance furnaces of the Clerc type or the Queneau type the conditions seemed to be quite different and probably more favorable.

Mr. E. G. Spilsbury emphasized that zinc is produced in the retort furnace not so much by contact with carbon monoxide gas, but by actual contact with elemental carbon itself. He recited some unsuccessful experiments which he had made some years ago on the use of carbon monoxide gas as reducing agent.

Mr. Woolsey McA. Johnson said that they had overcome their condensation troubles largely. Their average condensation factor (the ratio of weight of zinc in spelter produced to the sum of weight of zinc in flue dust plus ladle skimmings plus blue powder plus spelter) at Hartford was 75 per cent. They produced 1 to 5 per cent of blue powder and 15 to 20 per cent of flue dust. He emphasized that a sharp distinction should be made between blue powder and flue dust. One form of blue powder was particularly troublesome, namely, that due to the reaction between zinc and SO_2 or sulphur from the matte, and referred to his Canadian patent allowed February, 1913, in which a metallurgical description of "sulfidized chemical" blue powder and ways of preventing its formation is clearly given.

After a vote of thanks, proposed by Professor Kemp and seconded by Mr. Stoughton, to the speakers of the evening and to the Committee of Arrangements, the meeting adjourned. It was followed by an enjoyable informal social gathering in the rooms of the Institute of Mining Engineers.

The Wellcome Photographic Exposure Record and Diary for 1914 has just been issued by Burroughs, Wellcome & Company, of London and New York. (Bound in red cloth, price 50 cents.) As in former editions, a very large amount of useful information is condensed in this little and neat pocket guide to photography. Exposure, development, toning, fixing, printing, the various processes of production in warm tones and colors, and the methods of dealing with errors of technique are explained, particular attention being directed in the 1914 edition to the green and blue toning, and the production of various colors by development and other methods.

The cost of copper produced by the Isle Royale company in 1912 was 11.89 cents per lb. The average yield from the ore was 15.4 lb. refined copper per ton. The ratio of concentration at the mill was 93 tons of ore into one ton of mineral which yielded 71.43 per cent fine copper.

The Passivity of Metals

A Symposium Before the British Faraday Society

For the meeting of the Faraday Society, held on November 12, 1913, in London, a symposium of highly interesting papers on the subject of the passivity of metals had been arranged.

We herewith give abstracts of the papers presented. An account of the general discussion which followed will be given in the letter of our London correspondent in our next issue.

The following abstracts are taken from advance copies of the papers kindly sent to us by the secretary of the Faraday Society, S. F. Spiers, 82 Victoria St., London, S. W.

Introduction Into the Passivity of Metals

A paper forming a general introduction to the discussion had been prepared by Dr. George Senter, who pointed out the marked divergence of opinion which exists with regard to the interpretation or explanation of the experimental results on the passivity of metals.

The more important phenomena which have to be accounted for on any theory of passivity are as follows: The passive state is best known in connection with iron, cobalt, and nickel, but most, if not all the metals may be made to assume this state under suitable conditions. Passivity may be induced by immersing the metal in an oxidizing agent such as nitric or chromic acid, and in solutions of alkali hydroxides; also by anodic polarization in a great variety of electrolytes.

When the force producing passivity is removed the metal as a rule returns to the active state, slowly at first and then more rapidly, in some cases almost instantaneously. When the surface of a metal in the passive condition is scratched or rubbed, it regains its activity at once. Treatment with acids, cathodic polarization with hydrogen, and raising the temperature all favor return to the active condition.

A metal becomes much more positive (more "noble") when it changes from the active to the passive condition, and does not dissolve when the equilibrium potential is reached. On further increasing the anodic potential the metal may dissolve as a more highly oxidizing iron (e. g. chromium), or the current may be employed mainly or entirely in discharging anions. The rise of potential on anodic polarization is usually slow at first, and then there is a sudden rise of considerable amount, the metal almost becoming insoluble.

The nature of the anion has considerable influence. Thus the ions of oxidizing acids, such as NO_3 and ClO_4 , favor passivity, while Cl and Br have the contrary effect.

Three theories of passivity have obtained a greater or less degree of recognition:

(1) The *oxide-film theory* of Faraday. (*Phil. Mag.*, 1836, vol. 9, p. 53.)

(2) The *valency theory* of Krüger-Finkelstein (*Zeit. Phys. Chem.*, 1902, vol. 39, p. 104) and W. J. Müller (*Ibid.*, 1904, vol. 48, p. 577); according to this theory passivity phenomena are due to the change of a metal to a "nobler" modification.

(3) The *reaction velocity theory* of LeBlanc (*cit. f. Elektrochem.*, 1900, vol. 6, p. 472, and 1905, vol. 11, p. 9). In its most general form this theory states that passivity phenomena are due to slow rate of change (electrochemical or purely chemical) at the anode. In this form the reaction velocity theory is little more than a statement of the facts, and several special hypotheses have been put forward as regards the mechanism of the retardation. Thus we have:

(a) The *oxygen charge hypothesis* of Fredenhagen (*Zeit. Phys. Chem.*, 1903, vol. 43, p. 1; 1908, vol. 63, p. 1) and Muthmann and Fraenkenberger (*Sitzungsber. der Kgl. Bayerischen Akad.*, 1904, vol. 34, p. 201). The cause of passivity is to be sought in the slow rate of reaction between the anode and the oxygen liberated there, with the result that the anode becomes charged with the gas, or, alternatively, a metal-oxygen alloy is formed.

(b) The *anion discharge hypothesis*, according to which the main change at the anode is not the formation of metallic ions but the discharge of anions; the slow reaction of the dis-

charged anions with the metal produces passivity. The views of Sackur are based on the assumption of a primary anion discharge.

(c) The *hydrogen activation hypothesis* of Foerster (*Abhandlungen der Bunsen Gesellschaft*, 1909, No. 2), and of Schmidt (*Zeitsch. Physikal. Chem.*, 1911, vol. 77, p. 513), according to which the normal condition of iron is passive and it only becomes active under the influence of a catalyst. According to Foerster the catalyst is hydrogen; according to Grave (*Zeit. Phys. Chem.*, 1911, vol. 77, p. 513), a pupil of Schmidt, it is hydrogen ions.

(d) The *retarded ion hydration hypothesis* of LeBlanc (*Lehrbuch der Electrochemie*, 5th edition, p. 285).

Each of these different theories is briefly considered and discussed by the author. He finally concludes that in all probability it will eventually be found that no one theory will serve to account for all the phenomena of passivity.

Thus both LeBlanc and Foerster, although in the main favoring other explanations, recognize that the formation of insoluble films on the electrodes plays a part in some cases of passivity.

The hydrogen activation theory, which is perhaps most in favor at the moment, is undoubtedly valid to some extent, as the effect of nascent hydrogen in restoring the activity of passive metals is beyond dispute.

Whether iron entirely free from hydrogen is necessarily passive, as Foerster and Schmidt assume, would, however, appear to be still open to discussion. In particular, the activating influence of the free halogens (e. g., iodine in potassium iodide) is difficult to reconcile with this view, as it would appear that the metal in the absence of hydrogen is capable under these circumstances of sending charged ions freely into solution, which is contrary to the theory.

On the other hand, it should not be difficult to devise a plausible explanation of the *sudden* changes from the active to the passive state and vice versa on the basis of the hydrogen activation theory, whereas these changes are difficult to reconcile with any of the other theories. It is not easy to understand, for instance, how such sudden changes could occur on the basis of the ion hydration hypothesis favored by LeBlanc.

Anodic and Cathodic Retardation Phenomena

A paper by Dr. G. Grube, of the Institute of Technology of Dresden, Germany, discusses anodic and cathodic retardation phenomena and their bearing upon the theory of passivity.

There used to be a general tendency to assume that both the formation of metallic ions in the anodic dissolution of a metal and the transition from the ionic into the metallic state in cathodic deposition were processes which took place at practically infinite velocity. It was the merit of M. LeBlanc to have pointed out that, with certain metals, the passivity finds its explanation in the circumstance that these metals emit their ions of lowest valency into the solution at a greatly restricted velocity.

That the fundamental view of the theory of passivity of LeBlanc is correct, that it to say, that both anodic dissolution of a metal and cathodic deposition of a metal may be retarded phenomena, has within recent years been established by many experimental researches.

The author deals especially with the second part of Foerster's passivity theory, according to which the small reaction velocity marking the anodic dissolution and the cathodic deposition of passive metals does not alone suffice to focus the whole domain of activation and passivation, and that we are hence forced to assume a co-operation of positive and negative catalysts on the electrode.

The following important question thus suggests itself as concerning the problem of passivity: In how far is the velocity of reaction, and hence the variation of the potential in anodic and cathodic processes, influenced catalytically by the occurrence of small quantities of foreign substances on the surface of the electrode?

The author gives a review of a series of experimental re-

searches carried out by Foerster and his pupils during the last years.

In reviewing their results the author accentuates the following main points:

1. The cathodic deposition of the metals—in itself a slowly progressing reaction—can still more be retarded to a considerable extent by the simultaneous deposition of zinc or of hydrogen. The cause of these retardations is probably to be found in a change of the surface of the electrode, the change being characterized by the formation of unstable intermediate products of higher electrolytic solution pressure than the pure metals possess.

2. The circumstance that cathodic processes can materially be retarded by the occurrence of small quantities of foreign substances on the electrode lends essential support to the assumption that anodic processes may likewise be retarded by the formation of oxygen alloys on the anodes. In many cases, therefore, the cause of the anodic passivity will not be a mechanical closure (covering up) of the electrode surface by an oxide film, but the formation of an alloy consisting of the material of the anode surface and of oxygen, this alloy having a lower electrolytic solution pressure than the pure metal.

3. In the electrolytic oxidation of ferropotassium cyanide to ferri-potassium cyanide a strong polarization was always observed when the electrodes were surrounded by films of ferrocyanide or of oxides. These strong polarizations were not found with platinum, gold, nickel, cobalt, and copper in alkaline solutions. It may, therefore, be concluded that, in this latter case, the passivity is caused, not by an oxide film, but by an oxygen alloy on the anode.

4. The retardations observed in the anodic discharge of the halogens are likewise to be ascribed to alloys of the platinum anodes with oxygen.

5. The anodic evolution of oxygen shows what we have to understand by the passivating oxygen alloys. We may imagine that the oxygen combines to a small extent with the anode material to form oxides, which in their turn form, together with the unchanged electrode material, solid solutions, and therefore, one-phase systems of continuously variable composition and likewise variable electrolytic solution pressure. The oxide film theory contrasts with this view, since according to that theory the oxide formed would mechanically cover and shut off the electrode surface so that oxide film and electrode would form a two-phase system. The oxygen-alloy theory of the passivity thus seeks the cause of the passivity in a change of the chemical properties of the anode material, while the oxide-film theory finds the cause in a change of the mechanical properties of the electrode surface.

The Electrode-Volume Constant-Sum Hypothesis

A paper giving a "review and interpretation of recent experiments which extend and elucidate the domain of the passivity of metals," by Dr. D. Reichinstein, of Zurich, Switzerland, develops a theory which is an extension of the views of LeBlanc that it is velocity phenomena which condition passivity. The principal question discussed is how the transition is taking place from the active state of a metal into the passive state.

Several series of experimental facts are first discussed with respect to chemical polarization of reversible active metallic electrodes and with respect to "negative depolarization" (when a material added to the electrolyte does not chemically react with it and diminishes the current intensity instead of increasing it).

The author then passes over to a discussion of direct experiments on the passivation of metals.

"Surprise has often been expressed at the fact that a metal turning passive does not, at higher current density, show at least that anodic solubility which belongs to it at small current density. Let a passive metal be dissolved anodically at a low current density a to the extent of 50 per cent, and let it liberate oxygen, so that its dissolution takes place at $a/2$ amp./sq. cm. of metallic surface.

"When we increase the current tenfold, the dissolution will not proceed at the rate of 5a amp./sq. cm.; it does not even take place at the former rate $a/2$ amp., but at a much smaller rate. How is this to be interpreted chemico-kinetically?"

"Let us assume that a passive metal Me generates primarily oxygen. Two reactions are possible:

"The commencement of reaction (2) is designated 'passivity.' The example teaches us that passivity is not a result of two competing reactions, for both of which the velocity would increase with increasing oxygen concentration, but the passivity is caused by two reactions such that the velocity of the one reaction decreases with increasing O concentration, whilst the velocity of the second reaction regularly increases with increasing O concentration."

The author introduces the conception of the "electrode volume." The contact of an electrode with the electrode is assumed not to be formed by the solid metal, but by a solution (or alloy) of all those substances whose ions are represented in the electrolyte. The volume which this hypothetical alloy occupies in the electrode is designated "the electrode volume."

Now concerning this the following important hypothesis is introduced: "The sum of the concentrations of all the constituents of the electrode volume is always constant, whether the current flows or not."

The electrode volume is always fully saturated, and any new constituent, possibly introduced by the electric current, ejects parts of the old substances.

When a metal electrode is treated anodically the oxygen introduced pushes the metal atoms out of the electrode volume—the same will happen on the cathode by the H_2 introduced—and the chemical equilibrium prevailing before the current was flowing will be destroyed. The oxygen now begins to react with the metal atoms of the electrode volume. Let this reaction be of the form:

where Me and O are respectively an atom of the metal and of the oxygen of the hypothetical alloy, and H^+ concerns the electrolyte.

If a is the constant sum of the concentration of the constituents of the electrode volume, then the author shows that the following holds true:

When with a certain current density of the electrolysis the compensation process is so rapid that the oxygen concentration of the electrode volume does not rise above the value $a/2$ (which may be called the critical concentration), then there will be no reason to fear that another compensation process will set in, e. g., generation of oxygen (= passivity). When, however, the critical concentration is exceeded, the compensation process will necessarily be retarded, and the oxygen concentration will increase rapidly until a new compensation process sets in.

The case of solution of gold in cyanide is discussed in some detail.

Photo-Electricity and Passivity

A paper by Dr. H. Stanley Allen, of the University of London, deals with "the photo-electric behavior of iron and the theory of passivity."

The author points out it is not unusual to find that investigations in one branch of science serve to throw light on problems connected with some other subject. The author's research was undertaken in the hope that the study of the physical phenomenon of photoelectricity might assist in elucidating the century-old problem of the nature of "passivity."

The photoelectric effect here referred to is that which is known as the Hertz-Hallwachs effect. It consists in the loss of a negative electric charge or the acquisition of a positive electric charge by an insulated metal when the surface of the metal is eliminated.

The author's researches show that "iron which is chemically active shows large photo-electric activity, while processes

which render iron passive greatly reduce this activity. These facts are in good agreement with the theory which as well as the oxidation theory must be attributed to Faraday that the cause of passivity is to be found in the oxidation of the gaseous layer at the surface of the metal."

Hydrogen Theory of Passivity

A paper by Professor Gerhard C. Schmidt, of the University of Muenster, Germany, contrasts the oxide theory according to which metals are normally passive and passivity is due to a coating of oxide or oxygen on the metal, with the hydrogen theory according to which the metals in question are normally passive and become active only in the presence of dissolved hydrogen acting as a catalytic agent.

The latter view has recently been strongly supported by the author's pupils Grave and Adler on the basis of experimental investigations, but Flade has criticized the result as non-conclusive. The author now describes further experiments made by W. Rathart.

These experiments deal with the effect of a hydrogen charge on the potential and activity of a metal and further give the proof that a metal is rendered active by diffusion of hydrogen ions. This proof is given both for iron and chromium.

In this proof advantage was taken of the fact that when hydrogen is liberated electrolytically at one side of a piece of iron foil it rapidly diffuses through and alters the e. m. f. on the other side which is under test.

The author's views of the phenomenon of passivity agree with those of Grave. "Just as water or other liquids do not boil, even when their vapor pressure is equal to that of the superincumbent pressure, unless a catalyst such as air is present, so the metals which can be passivated dissolve rapidly only in the presence of a catalyst. The most important of such catalysts is hydrogen, since it is dissolved readily and in large amount by metals. Whether other gases are also catalytically active cannot at present be stated, since they are only absorbed to a very small extent by metals. Just as relatively small amounts of air initiate rapid evaporation in large quantities of liquid, so a small quantity of hydrogen can activate large amounts of iron, nickel, and chromium. It might be supposed that the hydrogen, like air in the case of boiling, forms a nucleus around which the ions of metal collect. Further investigation must decide whether this hypothesis is in accord with the facts."

Passivity and Reaction Velocity

In a paper on "the phenomena of passivity" by Professor Max LeBlanc, at the University of Leipzig, Germany, the author first reviews the oxide theory of passivity and enumerates the objections which have been raised against it. He concludes that it is evident that the hypothesis of an impervious layer, which covers the surface of the metal, thereby protecting it from contact with the electrolyte, is open to the most serious objection.

Professor LeBlanc then takes up the study of polarization measurements, when employing a system, metal-a nitro dilute solution of a metallic salt—metal (e. g., copper-copper sulphate solution—copper). It was expected that no appreciable polarization would take place in the case of short-time electrolysis with moderate current density. While this expectation was fulfilled in some cases it was not fulfilled in others. How can this be explained?

In considering the action at the anode, it is conceivable that primarily no metallic ions are formed, as is generally supposed, but that the electrical process consists of a discharge of negative ions and the chemical process of an interaction between the non-electrified radical and the metal. The potential difference would, according to this view, depend upon not only the concentration of the negative ions, but upon that of the separated non-electrified radical, and consequently upon the velocity with which the latter reacts upon the metal.

In a similar manner the cathodic polarization can be explained. When the current passes, the free ions separate, which

must, in the state of equilibrium, according to the law of mass-action, always be present in addition to the hydrated ones. Consequently a diminution in concentration and then polarization follows, owing to the insufficiently great speed of the formation of free from hydrated ions.

An analogous explanation may be made for the phenomena of passivity. With passive metals ionic hydration occurs so slowly at the anode (a certain amount of solution nearly always takes place), that the concentration of free ions and, therefore, the potential difference, becomes so great in a short time that visible separation of the negative radical or of oxygen can result.

From this point of view we must henceforth understand by passivity phenomena all such as result from chemical polarization. Passivity is not the exception, but the rule, and it is not connected with oxygen-containing anions, as was supposed, but it takes place also with chlorides and other solvents, and especially it can also take place at the cathode.

Anodic Oxygen and Oxide Films

A paper by Professor E. P. Schoch, of the University of Texas, discusses "the mechanism of anodic reactions and the behavior of iron and nickel anodes."

The mechanism of any anodic reaction is considered to be the direct attack of the anode by the anions. From Guenther Schulze's experimental work on the electrolysis of phosphate, borate, etc., solutions with an aluminum anode (*Ann. d. Phys.*, vol. 28, p. 789) the conclusion is drawn that a film, or cover, over the surface of an anode will hinder or prevent the direct access to the surface of the metal of complex anions and will bring about the formation of oxygen ions from them. The latter pass on to be discharged on the surface of the metal.

This gives all the facts necessary for the explanation of the chemical change of any anode in any electrolyte. Briefly this explanation may be stated as follows:

"With a clean anode surface the anions come in direct contact with the metal, react with it, and give up their electrons; the rapidity of the reaction and the final products obtained will vary greatly with different metals and different anions.

"The product may be so rapidly formed and so rapidly dissolved that other anions may have unhindered access to the surface. Again the reaction may be slow, or the product may dissolve slowly, or the latter may be insoluble, or it may be hydrolyzed into an insoluble compound, so that other ions may find their progress to the anode more or less obstructed—a condition that may naturally be brought about in almost any case by a sufficiently great current density.

"Many complex ions which are prevented by the obstruction from reaching the surface of the metal will dissociate into an equivalent number of oxygen ions, which reach the surface of the metal more readily.

"Upon discharge these oxygen ions may form the oxide of a metal (as with copper in sulphate electrolytes), or they may form partly an oxide and partly oxygen (as with platinum in sulphate electrolytes), or they may react so slowly that the discharged oxygen still in contact with the metal becomes gradually more condensed as more oxygen ions are forced into the same area with a greater potential difference until finally gaseous oxygen, or perhaps some higher oxide of the metal is formed.

"In the absence of any oxide skeleton the layer of oxygen, on thickening, will soon allow bubbles of gas to escape—as is probably the case with platinum, iridium, etc., in which the oxide formed is within the body of the metal.

"But when a non-conducting oxide skeleton is formed the layer of gas may accumulate to a relatively great thickness as the oxide skeleton grows, and this may prevent more or less completely the passage of any ions to the electrode.

"Finally, if the oxide is oxidizable to a conducting (per-) oxide then a suitable concentration of oxygen produced by its discharge under a sufficiently great potential will produce this peroxide and oxygen gas will then be evolved from the new surface of the peroxide.

"The actual existence of this latter state of affairs has been beautifully demonstrated by E. Mueller (*Zeit. f. Electrochem.*, vol. 13, p. 133) who showed that a copper anode in sodium hydroxide solutions forms hydrated cuprous oxide as long as the current density is small enough; but with a larger current density the anodic potential becomes more noble, copper peroxide is visibly formed on the anode, and then oxygen is evolved from the surface of the latter. It appears that the "oxygen-producing" discharge of ions on peroxide anodes is a rapid reaction, because no great hindrance is observed even with great current densities.

"This beautiful demonstration by E. Mueller of the relations between active and passive copper indicates that the phenomena which characterize the attainment of passivity by some metals in certain electrolytes appears to be nothing but the regular behavior of anodes under the existing conditions."

Professor Schoch has reached the same conclusion from his study of the behavior of iron and nickel anodes in various electrolytes. (*Zeit. f. Phys. Chem.*, vol. 58, p. 301; *Am. Chem. Journ.*, vol. 41, pp. 203 and 235; *Jour. Phys. Chem.*, vol. 14, p. 739.) A review is given of the experimental facts which are then explained by the general theory of anodic reactions outlined above.

"No special attempt was made to state in what particular form the oxygen obtained by the discharge of oxygen ions is present on the surface of iron or nickel anodes, that is, whether it is present as free oxygen or as oxide. To the writer there do not appear to be any facts which establish one view over the other. The assumption of a free oxygen film is perhaps a trifle simpler than the assumption of a formation of an oxide, but the possibility of the presence of an oxide has not been disproven."

Professor Schoch finally discusses briefly the hydrogen catalysis theory.

"Possibly the best experimental evidence for a decision between the hydrogen catalysis theory and the theoretical views we have here advanced in the following.

"A chromium anode that has become passive with reference to the formation of bivalent ions does not become active again to form trivalent ions, but does become active again to form chromation.

"An iron anode that has been made passive with reference to the formation of bivalent ions does not become active again to form trivalent ions. However, when electrolyzed in acetate, or oxalate solutions the electrode becomes active again (that is, the metal dissolves again extensively) at potentials considerably below those (more noble!) at which it has ceased to be active before and at which it is usually passive in other electrolytes. The same thing is true of nickel (*Jour. Phys. Chem.*, vol. 14, p. 719; *Jour. American Chem. Soc.*, vol. 30, p. 1737)

"In all three instances above the activity at the lower potential is due to a reaction which consumes oxygen and thus lays the metal surface bare. This is plainly the case in the formation of chromations. In the other examples the activity of the iron or nickel reappears when the potential is low enough to oxidize the acetate or oxalate, and when the oxygen is removed to oxidize these substances, then the metal surface is exposed and is subject to the attack of the anions."

Passivity and Electrolytic Valve Action

A paper by Dr. Günther Schulze, of the Reichsanstalt, deals with the relation of passivity to the phenomenon of electrolytic valve action. The author emphasizes the remarkable analogy between the phenomena of valve action and passivity which follows from the assumption that valve action is caused by an insulating film and consequently a gas layer while passivity takes place if the film shows metallic (electronic) conductivity together with a limited or negligible solubility in the electrolyte.

The consequence of the metallic conductivity of the film is that it cannot grow much above molecular size and must be almost undetectable by optical or mechanical means. The oxygen developed at its outer surface covers it more or less and protects it against the electrolyte when it has been formed

Thus the current may be decreased below the critical forming value without restoring activity.

The behavior of iron in H_2SO_4 of different concentration is of special interest. In dilute sulphuric acid it shows passivity. In concentrated acid valve action. In intermediate concentrations an unstable valve action is succeeded by stable passivity. In dilute solution the anions SO_4 may form an oxide of iron by the aid of the water. In concentrated solutions the small amount of water present is not available for this reaction, as it is bound to the sulphuric acid itself. Therefore, ferric sulphate must be formed. This insulates and causes valve action.

"Therefore I hold: Valve action is caused by an insulating skin of ultra molecular thickness with a thin gas layer within it; passivity by a conducting skin of molecular thickness with a molecular gas layer upon it."

Electric Furnaces, Their Design, Characteristics and Commercial Application

By Woolsey McA. Johnson and George N. Sieger
Buildings for Electric Furnace Plant

The character of building depends entirely on the stability and certainty of operation. For a small experimental plant a wooden shack 16 ft. x 32 ft., 10 ft. to eaves, 16 ft. to ridgepole, costing \$140, is good enough.

When the work has a reasonable certainty of continuing two or three years an edifice like the new furnace building of the Continuous Zinc Furnace Company, 32 ft. x 60 ft., built of heavy braced wooden framework, with a roof supported on strong wooden trusses, sides, ends and roof covered with No. 26 galvanized sheet steel, is neat and serviceable. This building was designed by F. E. Waterman, architect, of Hartford. The total cost without architect's fee was \$608. This did not include concrete floor, which was afterward laid on a floor of ashes and slag.

For a more permanent structure, a structural steel framework covered with galvanized sheet steel is to be recommended. This will cost nearly double what a similar structure of spruce framework costs. Its main advantage lies in the fact that it is fireproof.

For a permanent structure designed to last ten to fifteen years, a structural steel framework with curtain walls of red brick or hollow tile with a concrete roof covered with tar and gravel or covered with tar and gravel on a felt covering is ideal, but this will cost about 2.5 times what a galvanized-iron structure costs.

Rough figures per cubic foot for average conditions in the United States (and these are not far from wrong for any place as where lumber is cheap, supplies are apt to be dear, and where labor is low it is apt to be inefficient) are given below:

Kind of Structure.	Cost Per Moderate Height Per Cubic Foot
Wood shack	\$0.02 to \$0.025
Galvanized sheet on wooden frame- work	0.30 to 0.35
Galvanized sheet on steel frame- work	0.00 to 0.075
Hollow tile walls steel framework	0.10 to 0.150
Concrete roof covered with tar gravel.	

FIRE PROTECTION

In any electric-furnace plant, as in any metallurgical plant, while the building is in course of erection, it is good business to install a fire hose in a corner or a number of them in corners. These hoses should have a large pipe connection with a quick-turning shut-off valve to city main or system that has good water pressure back of it.

A safe rule is if one puts in 1-in. fire hose to connect it to an 1½-in. pipe. If one wishes to exhibit a great pretence of accuracy and scientific engineering, multiply the diameter of fire hose by $\sqrt{2}$ or 1.414 and then add 10 per cent, guessing at the final proper size for pipe connection. The main point is

to have the pipe connection considerably bigger than the fire hose.

The fire hose with nozzle is coiled on a framework and placed in a box made of double walls of sheet steel or asbestos-wood," and having space between inner and outer walls filled with mineral wool. In the bottom of these boxes is placed an electric heater of 500 watts capacity. If the door shuts tightly, and the heater is on, the fire hose will never freeze up. The nozzle should be securely fastened to the hose so that it cannot be taken off to furnish water for the masons or for mixing concrete.

Around the walls as a further fire protection, small chemical extinguishers using acid and soda ash or "squirt guns," using carbon tetra-chloride, may be provided. These are first rate for small incipient blazes. In case of a fire the first thing for the superintendent to do is to see that high-tension switches are thrown, so that water can be played without men getting "shocked," and then to save any note books and measuring instruments from damage by water or fire. The men will use hoses with zest, energy and dispatch, and the superintendent can smoke his pipe.

The Continuous Zinc Furnace Company has had twenty-seven fires in the past six years and none of them has caused damage amounting to more than \$25. If it had not been for efficient fire protection the amount of damage undoubtedly would have been serious. With such a protection the only damage from fire can come when nobody is at the plant, as during the night when no runs are going.

FOUNDATIONS FOR ELECTRIC FURNACES

In view of the hazardous and uncertain element in electric-furnace work, especially at its inception, emphasis must be laid on the necessity of having foundations which are above all question. Test pits should be dug and a bearing value of ground measured by well-known engineering methods. Then a large factor of safety should be employed.

For a small furnace, weighing from 1 ton to 5 tons, a bearing value of 1000 lb. per square foot is a conservative assumption. In this case a hole 30 in. deep and 48 in. square can be dug, filled with concrete (a 1:1:2.55 mixture is all right). This will hold up 16,000 lb., unless the ground is soft on one side and hard on the other.

A cheaper way is to put in large blocks of masonry or of concrete from demolished buildings and pouring a wet mixture of sharp sand and cement (1 to 1). Old wire, barrel hoops, old pieces of pipe thrown in tie the piece together and make a monolith.

When a larger furnace is to be supported an excavation 48 in. to 72 in. deep can be made. In such a case old girder rail-tied together with corrugated iron bars in regular fashion and a whole mass of 1:3:6 concrete tamped in. Where special strain comes a mixture 1:2:4 can be used in the monolith.

This scheme is good engineering where a total load of 125 tons to 175 tons is to be held up. Fig. 1 shows this.

But when loads exceed 175 tons, there is a risk of uneven settling and piles must be used. A pile will hold up from 10 tons to 40 tons, according to size of pile and according to force of blow that pile-driver used can deliver. The pile should be capped with a steel hoop or "hat" of cast iron. Above the pile special reinforcing should distribute the upward forces in the form of an inverted pyramid. On top of this should come a platform of reinforced concrete.

The reason why piles are advisable is that the certainty of their holding up the load is as absolute as anything can be.

POWER FACILITIES

The authors believe that in general the power facilities should have 20 per cent. capacity in excess of the normal rating of furnace. There always comes a time in the operation of a furnace when it pays to force the furnace, for the reason that the furnace is cold and working slow, or because the ore is especially easy-working and a little forcing will increase daily tonnage. With this reserve power capacity above normal furnace demands the furnace will be operating all the while at its maximum commercial efficiency.

The great tendency in design of electric furnaces is to underrate them, either because of the fact that thermal efficiencies are usually estimated at too high a figure or because heat-balance sheets are made that are too optimistic. Moreover, the power-factor or load-factor rarely comes up to what is hoped for or the drop in potential from switchboard to electrode is greater than was originally estimated.

It may seem paradoxical with a 200-kw furnace to have a 250-k.v.a. transforming or generating apparatus, in view of the fact that any well-designed electrical apparatus is capable of

(2) Raising the voltage up or down by varying field voltage of electric generator or by cutting in or out resistance in field circuit.

(3) Where an electric transformer is used, use may be made of cutting out number of turns in primary or secondary winding or by changing either of these from series to multiple or to semi-multiple, or increasing or decreasing the magnetic reluctance of circuit.

(4) By using a water-rheostat or other variable resistance in series with the electric furnace.

FIG. 1.—FOUNDATION PLAN FOR ELECTRIC FURNACE

being overloaded for short periods tremendously. But if we apply first principles of commercial science we will find that the following reasoning applies:

(1) Electric furnace processes if successful at all have a large margin of profit.

(2) That which makes them successful at all is the powerful metallurgical effect of the electric current.

(3) Therefore, the supply of this should be ample to carry operation along at a maximum rate of daily tonnage at will of the manager.

VOLTAGE REGULATION

There have been few large electric furnaces built that operate at a constant voltage. The reason for this is the fact that the voltage depends on the resistance of the furnace and that this resistance depends greatly on the temperature. Substances that do not conduct cold at all conduct well at high temperature. To use a striking example, a 100,000-volt modern porcelain insulator would break down at 25 volts at 1400 deg. C. With this tremendous change from a perfect insulator to a good conductor, it is evident that the regulation of voltage must be under good control, for temperature is sure to vary from time to time.

Now, one way to do this is to have some automatic regulation of the length of circuit through which the electric current plays. The best example of this is seen in the classical steel furnace of Siemens. As lately practiced by Girod and Héroult in the modern electric steel-refining furnace, the voltage is kept nearly constant by moving the electrode automatically up or down by a relay-controlled motor. The relay is actuated by a device which depends for its motion on some function of the electric current.

When no such internal regulation is used, external voltage regulation is employed. This can come from the following scheme of design

(1) Speeding up or down the prime-mover such as steam engine. Such a process can only be used well when one furnace is operated tied electrically to a generating set.

When doing electric zinc furnace work for the Lanyon Zinc Company in 1903 and 1904, one of the authors used this electrical layout.

An old 75-kw. Westinghouse alternator was belted to the line shaft of the power plant. The field of this was excited by an old Edison direct-current generator. The field current of the former could be controlled by one rheostat and field current of the latter by another rheostat so that any voltage from 300 to 1000 could be obtained from the alternator at a maximum of 125 kw. with a minimum of 45 kw.

This high-tension circuit was put directly on the electric zinc furnace which was of ore resistance type making an infusible residue, when a furnace was started up from the cold.

FIG. 2.—WIRING DIAGRAM FOR ELECTRIC ZINC FURNACE

As the voltage decreased this current was transformed by means of four 25-hp transformers (ratios 1100 to 220 and 1100 to 110). So a minimum voltage of 30 volts at 45 kw was at hand. The entire set gave thus a minimum of 45 kw at any voltage from 30 volts to 1800.

This scheme of electrical connections is shown in Fig. 2. It is a good layout for experimental work where plenty of surplus mechanical power is at hand.

ELECTRIC FURNACE TRANSFORMERS LOW CAPITAL COST THE ESSENTIAL

Electric-furnace transformers are a special department of electrical engineering. In general cases a number of taps are brought out from the primary winding and by some switching device these can be cut in or cut out so as to make a varying transforming ratio and a variable voltage on furnace circuit.

A heavy double-throw switch on the secondary puts the secondary coils in series or in multiple, thereby changing the transforming ratio 100 per cent in one operation. This is the usual design.

Special devices such as choke coils in series or in shunt in the primary or some device that will change the magnetic reluctance of the transformer core may be employed.

The main consideration in designing an electric-furnace transformer is to make a practical machine and *one of low capital cost*. It is evident that with power at 2 mills to 4 mills per kw-hour little money is saved by increasing the electrical efficiency from 96 to 99 per cent.

Rather should one pay a few more dollars on the power bill and cut down hundreds of dollars on the interest and depreciation account, for in a new industry this figure the authors place at 20 to 35 per cent per year.

Good commercial design of an electric-furnace transformer has this commercial fact incorporated in itself.

The subject of electric-furnace transformer design is an important one and will be made the subject of a forthcoming separate article of this series.

The transformer plant should be either outside on a platform or in a separate building away from dust and smoke.

The design of a transformer station of an experimental plant, of course, is quite different from that of a regular furnace plant. Here the main point is to buy as little as possible and it is good business to waste power seemingly quite recklessly but really scientifically.

Any experimental plant should have on the high-tension circuit either an oil-switch or a "disconnecting" switch on pole-better both. In time of trouble these can be "pulled" and "juice cut off" so that repairs can be made in safety.

Fuses should be eliminated or of large capacity so that nothing but a prolonged short-circuit will blow them.

High-tension circuit breakers made so as to break the current instantaneously and placed so that all breaking of the furnace current is done on the high-tension side are the right things to install.

At the plant of the Continuous Zinc Furnace Company there

FIG. 3. DIAGRAM FOR ELECTRICAL CONNECTIONS

are four 50-kva transformers on each phase. The voltage ratio is 2400 to 240 to 120 on each transformer. Each phase has the transformers arranged in two sets of two transformers in series.

The various voltages on the bus-bars are secured by connections made both on the primary side and on the secondary side.

Provision is made for connecting the sets together in parallel when 60 volts are desired, or in series when 120 volts is wanted. The two transformers of each set are connected in parallel 240-volt connection can be made by disconnecting the bus bars and putting the primaries of the four transformers of each group in multiple, and the secondaries of each set in series.

FIG. 4.—WATER RHEOSTAT

Intermediate voltages between zero and 60, or 60 and 120, 120 to 240, are obtained by the use of water rheostats.

Recently there has been installed an arrangement of disconnecting switches on the primary side so that the primary of each of the four transformers can be connected in series, whereby 30 volts on the secondary is obtainable.

Thus there is at disposal out of standard apparatus that will give 125 kva as a minimum at any voltage from 30 volts to 240 by imperceptible gradations.

Fig. 3 shows this.

WATER RHEOSTATS

A strong, durable and efficient water rheostat has recently been constructed at the Continuous Zinc Furnace Company's plant. The vat is 72 in. x 46 in. x 48 in. and is made of cypress wood 3 in. thick. All joints were splined and white-leaded. The whole is securely held together by the use of 5/8-in. rods running vertically and horizontally. The vat is designed to regulate the voltage of two furnace electrodes on the same phase.

Regulation is obtained by the use of three electrodes made of 3/8-in. perforated boiler plate 40 in. x 42 in. One of these, the neutral, is located in the center and is stationary. The other two are movable. The movable plates are attached to No. 1 Standard Fairbanks trucks, the tracks for same being 2-in. tee bars running across the top of the vat. The trucks are easily moved in either direction by means of ropes and pulleys.

Electrical connection is made to the boiler plates by first cleaning a small area of the plate and copper-plating it. A small piece of copper bar is then soldered to it and the connection is given mechanical strength by the use of a bolt. Fig. 4 shows this.

BARREL RHEOSTAT

An ordinary strong barrel (gun or whiskey) is used to an advantage in the construction of a cheap and serviceable water rheostat. In rheostats of this type used at Hartford, the fixed lower electrode consisted of a coil of 1000 copper wire about 3 ft. in length

on which was placed an iron disk, 15 in. in diameter. A water-tight connection was made through the barrel by tightly screwing a brass nipple in the barrel, running the copper wire through this, solder being used for the seal. The copper wire was tinned and the inside of the brass nipple was tinned before pouring in the seal of solder.

The movable electrode was made of a perforated disk 15 in.

thick and 15 in. in diameter, connected to a 1-in. pipe as shown. To the upper end of the pipe a four-way was attached.

This served the double purpose of a means of support and for electrical connection.

The whole was suspended from a pulley by a $\frac{3}{4}$ -in. hemp rope to the four-way.

Electrical connection to movable disc was effected by using a brass nipple and a flexible cable which was soldered to the brass nipple.

The idea of having copper wire enter through the bottom in a perfect seal, so as to avoid troubles of internal short-circuit, was suggested first by Mr. Cole, electrical engineer of the Johns-Pratt Company.

All rheostats should be placed outside, using soda ash, which is non-corrosive during all months save December, January and February, when common salt, which is slowly corrosive but which will not freeze, should be used as the solute to give requisite conductivity.

The big water rheostats will absorb without trouble 40 kw

FIG. 5.—BARREL WATER RHEOSTAT

each. A barrel rheostat will absorb in constant service only about 5 kw.

Fig. 5 shows the Continuous Zinc Furnace Company's barrel rheostat.

BUS-BAR AND CABLES

Undoubtedly the cheapest way to carry electric-furnace current is by bus-bars. These sell at 2 cents to 4 cents above the price of ingot copper and will carry at least 25 per cent more than the same amount of copper in a bare cable and nearly double the amount of copper in an insulated cable. They can be bolted or clamped together. At the Hartford plant of the Continuous Zinc Furnace Company bus-bars are used for almost all switchboard work. We have a lot of right-angle bends and other short pieces, which are used just the way a plumber uses T's, L's, etc.

These are fastened together with malleable iron carpenters' clamps 4 in. to 6 in. in size. It is surprising how serviceable these ungainly circuits are, especially if care has been employed to see that the contacts are bright and smooth as all copper contacts should be. Bus-bar circuits are interlaced to cut down the self-induction and to raise the "power factor."

To the furnace, of course, flexible cables lead to electrode connection-clamps. The lugs for these should be of high-conductivity bronze or forged copper. Where possible the cable should be pressed or forged into place or brazed into lug. Soldering is not the right way to do it, although it can be used. A special electric furnace cable with a core of asbestos rope of about perfect properties and characteristics is made by the General Electric Company.

Intercrystalline Cohesion of Metals

A second paper on this subject was presented by Dr. W. Rosenhain and Mr. D. Ewen at the recent meeting of the (British) Institute of Metals in Ghent, Belgium.

This paper is a continuation of a research undertaken in order to test by experiment the theory that the crystals of a metal are held or "cemented" together by thin films of the same metal in the amorphous or undercooled liquid condition.

In their previous paper the authors obtained evidence in favor of this theory from the behavior of metals when heated in a high vacuum. Since then the theory has received further support from the researches of Rosenhain and Humfrey on the tenacity and fracture of mild steel at high temperatures (Iron and Steel Inst., May, 1913). There it was shown that at high temperatures the type of deformation and fracture obtained by any but very rapid strains was entirely different from the type found at low temperatures. In the latter type both deformation and fracture occur principally within the crystals, while the boundaries act as stiffening and strengthening ribs; at high temperatures, on the other hand, the crystals remain almost undeformed while movement and ultimate fracture occur principally in the intercrystalline boundaries.

Detailed consideration of the observed facts shows that they can be readily explained by the amorphous cement theory—the cement being strong and hard at low temperatures, but, like all very viscous fluids, becoming soft and mobile at high temperatures.

An extension of this idea shows that at a sufficiently high temperature in all pure metals the "cement" must become so fluid as to possess no appreciable strength, while the crystals still retain a definite degree of strength and hardness. It follows that at such temperatures the crystals, even of the most ductile metals, should be capable of being pulled apart without undergoing deformation and the metal should exhibit extreme intercrystalline brittleness.

This has been experimentally verified in the case of lead, tin, aluminium and bismuth, photographs of the strikingly intercrystalline fractures thus obtained being given in the paper—the brittle fracture of lead at 323 deg. C. (melting point 327 deg. C.) having an appearance like that of a brittle casting. These experiments show that the well-known brittleness of metals near their melting points is due to loosening of intercrystalline cohesion as indicated by the amorphous cement theory.

The authors deal with the suggestion that impurities concentrated in the crystal boundaries may affect these results and show that this objection cannot apply to their experiments and they strengthen this view by showing that a pure eutectic alloy (that of lead and tin) exhibits analogous phenomena.

Microchemistry of Corrosion

A paper by Dr. Cecil H. Desch and Mr. Samuel Whyte, entitled "The Microchemistry of Corrosion. 1: Some Copper-Zinc Alloys," was read at the recent meeting of the (British) Institute of Metals.

Experiments are described in which uniform areas of various alloys are corroded for a definite time under the influence of an electric current. The material dissolved by the electrolyte is analyzed, as well as the adherent metallic deposit. The surface of the alloy is also examined microscopically before and after the removal of this deposit. Only a few milligrams of material have to be used for each full analysis.

The alloys used in the first series of experiments are beta alloys of copper and zinc with and without the addition of tin or iron. Quenching from above the transformation point (470°) increases the corrosion, although the action is slightly retarded at first. Iron hastens corrosion, while tin retards it. The influence of the latter element, however, is chiefly mechanical, by means of the formation of a tough, adherent layer of basic salts, which serves as a protective coating.

The microscopic appearance of the corroded surfaces is characteristic.

The Iron Blast Furnace and the Characteristics of Its Fuels

Fundamental Conditions—Definition of Blast Furnace—Classification of Fuels Used—Essentials of Plant

By J. E. Johnson, Jr.

Iron is one of the most common elements in nature. Geologists state that it comprises 7 per cent. of the earth's crust and that there is strong proof that the whole interior of the earth below a depth of a few miles is composed of iron. The vast segregations which have gone on throughout geological time have resulted in concentration of iron to all degrees from the lowest up to 72 per cent. The concentration never exceeds this degree for the reason that iron is unlike most other of the useful metals in one important particular. It is seldom or never found native on the earth, except in the form of meteorites which have fallen from space.

This is in consequence of the great affinity of iron for oxygen, with which it will unite under almost all conditions of temperature and chemical environment found on the earth. This brings us to the fundamental fact in the metallurgy of iron which distinguishes it from all the other useful metals.

Its only ores are its oxides. The sulphides which are so important in the occurrence and metallurgy of other metals are not regarded as ores of iron, but only as ores of sulphur.

When the sulphur has been burnt off for conversion to sulphuric acid the iron takes up oxygen to replace the sulphur and becomes an oxide. These artificial oxides then become iron ores under certain conditions and with certain limitations which will be considered later.

But the use of iron sulphide as iron ore either by burning the sulphur off to waste, or directly in the furnace, as is so commonly done with the sulphides of other useful metals, is entirely unknown in the metallurgy of iron.

It is true that carbonates are important sources of iron in Europe, but their carbonic acid is not strongly held and before they are charged into the furnace are driven off by an oxidizing roast which converts the resulting ferrous oxide FeO to ferric oxide Fe_2O_3 . This reaction takes place so easily that it will occur slowly under ordinary atmospheric conditions, but with the slight modification in that case that the ferric oxide takes up water of combination and becomes limonite.

More than 90 per cent. of the world's production of pig iron is derived from ores which occur in nature as oxides and the remainder comes from the roasted carbonates and the ferric oxide or "pyrite cinder" derived from the sulphides.

From the point of view of the blast-furnace, therefore, it is correct to say that the only ores of iron are the oxides.

The removal of the final traces of oxygen from iron is so difficult that it can commonly only be done with an expensive gas like hydrogen or methane or by solid incandescent carbon and as the latter is commercially so much more available we may say that industrially iron is reduced only with solid carbonaceous fuel.

Fundamentally then the metallurgy of iron consists of the reduction of the oxides through the use of solid carbonaceous fuel. This operation is carried on to the extent of a few hundred tons per year in the Catalan forge and to the extent of some sixty or seventy million tons in the blast furnace which, therefore, constitutes the foundation of the iron industry.

The blast-furnace is a shaft furnace, the "high-furnace" of France and Germany, and takes its English name from the fact that the air to support combustion must be forced into it under pressure because of the resistance to the passage of the combustion gases offered by its high shaft filled with material. It became, therefore, a "blast" furnace as opposed to a draft furnace, obtaining its air through chimney draft.

The blast-furnace is historically the outgrowth of an attempt to utilize the waste heat of a "low furnace" or Catalan forge so as to reduce the fuel required for the latter and is probably the first industrial application of what is called the counter-current principle.

This may be defined as a method of transmitting the properties of one mass of matter to another by causing the two masses to travel past one another in opposite directions in intimate contact. This process leads naturally also to continuous as opposed to intermittent operation, one of the great desiderata of industrial processes.

This practice has so long and so universally prevailed in the iron industry that it has caused us to overlook one of the most important facts concerning the blast furnace and one to which we shall have occasion to revert many times; namely, that it is an apparatus in which we have merged two distinct processes. First, the reduction of iron oxide to metallic iron. Second, the melting of the reduced material.

The deep fire necessary for melting the "iron sponge" or reduced iron in a reducing atmosphere (without which it would instantly become oxidized again) was not unlike a gas producer in its construction and operation, and consequently discharged a hot gas rich in CO .

The utilization of this heat was the object sought by those early unknown pioneers who added the shaft above the low hearth or Catalan forge, increased the blast pressure to suit and so transformed it to the blast-furnace.

The fuel economy desired was obtained to such an extent that the low hearth declined to a position of insignificance, although the change brought many other changes not contemplated by the pioneers, some of which were not to their liking.

Most of these must await discussion in a subsequent article, but one was vastly important because it made a radical alteration in the character of the product, and in the process. The original product was tough and pasty, could not be melted but could be "wrought" directly under the hammer, while the product of the improved furnace could not be worked under the hammer, either hot or cold, passing immediately from the brittle solid state to the liquid state in which it could be "cast" or poured. Hence the names of the two principal varieties of iron, "cast" and "wrought."

The production of the iron in the liquid condition contributed further to the continuity of the process since the iron could be allowed to gather in a pool at the bottom of the furnace instead of requiring to be worked out in lumps or "lumps" with fire tools, when ready; and the subsequent introduction of a fresh charge of ore.

The shaft-furnace along with these advantages brought a requirement of far-reaching importance. The column of stock must be penetrable by a considerable gas volume at a reasonable pressure. This requirement is just as important to-day as it was in the early day of which I have spoken, though it must be confessed that our ideas of a "reasonable pressure" have undergone great changes.

This penetrability of the stock column may be seriously if not fatally impaired by either of two conditions.

First, the presence of tarry or sticky matter which would fill up the interstices of the charge and make it practically gas-tight.

Second, great fineness of the charge, either of the ore or of the fuel. Moreover, the fuel is subject to a certain solvent action by the gas as will be described later, and this is more active in proportion to the fineness of the fuel so that serious loss occurs if the latter be too fine.

The two principal fuels available, wood and bituminous coal, in their native condition both contain tarry material, but in very varying quantities. The vast majority of their varieties are, therefore, not adapted to use as furnace fuels without preliminary treatment to drive off the tar, so that this condition is industrially of paramount importance.

We can now combine all these necessary conditions to form a fundamental definition as follows:

The blast-furnace is a vertical shaft-furnace blown with air under pressure for reducing iron from the oxides and delivering it in a liquid condition. Its fuel must be not only solid but in lumps of considerable size and must be sufficiently free from tarry components to permit the passage of the gas resulting from the combustion in its hearth.

In addition to these fundamental requirements of a blast-furnace fuel there are others of nearly equal importance.

The three characteristics next in importance to those mentioned are first, purity, particularly freedom from sulphur and phosphorus. Second, porosity or ratio of surface to mass. Third, physical strength or resistance to crushing.

The reason for the importance of *freedom from sulphur and phosphorus* is that next to carbon these two elements exert the most important influence of any of the common constituents in steel both being destructive of quality if present to an extent greater than one-tenth of one per cent. If present in the pig iron of which steel is made they cannot be eliminated at all when certain processes are used and in the others only with increased difficulty and expense. In foundry irons phosphorus is not objectionable within certain limits, but sulphur is as much so as in steel.

The blast-furnace may be so operated as to remove the sulphur in the charge but only with increased cost for fuel and flux and with decreased output and in some cases with reduced quality.

This is not the case with phosphorus, virtually all of which present in the charge goes into the pig iron, in normal operation.

For these reasons sulphur in fuel is always bad and progressively worse as its amount increases, although its removal is possible.

Phosphorus in the fuel, on the other hand, may not be objectionable in any given quantity for certain iron, but if objectionable is prohibitive of the use of that material because its removal in the blast-furnace is impossible.

The importance of *porosity* of the fuel comes from the fact that the velocity of combustion of carbon in air is not infinite but limited. Only a limited amount of carbon per unit of surface exposed can combine with oxygen no matter how favorable the conditions and in order to secure the rapid combustion necessary to produce high output from a given size of furnace, much surface must be exposed by the fuel.

This cannot be done by reducing its size and so increasing the ratio of surface to volume and mass except to a very limited degree for reasons already explained, and high combustion velocities can, therefore, only be obtained with porous fuels.

The porosity also has a direct bearing on the volume of given weight of fuel, and this also will be shown subsequently to have an important influence on the operation of the blast-furnace.

Physical strength is important because without it no matter how large the lumps of fuel may be initially they are broken by the superincumbent weight of the charge column as the coke descends into the furnace and we have that condition of fineness of fuel which is so objectionable.

On account of the fundamental effects on the operation of the furnace and the quality of the iron caused by these chemical and physical variations in the fuel used, furnaces and the irons they produce are commonly and quite properly classified by the fuels used. These are in the order of their importance as follows: Coke, charcoal, anthracite, raw coal.

Coke

This subject is so important that large volumes have been written about it to which those in search of profound information are referred. It is only possible to give a bare outline here.

Coke is a light, very porous fuel produced by the distillation of mineral coal containing sufficient bituminous matter to cement together the whole mass at a certain temperature.

The distillation drives off nearly all the volatile matter and good coke consists almost entirely of fixed carbon and ash. Coke is made in four ways, of which only two are metallurgically important.

First, in *heaps or mellers* on the ground. These heaps are covered with turf and dirt to prevent the access of sufficient air for complete combustion. The limited combustion permitted generates heat enough to drive off the volatile matter from the

remainder of the coal and coke results, but the yield of coke per ton of coal is very small, the cost is high, and the valuable by-products are of course completely wasted in this process.

For these reasons this process is not in industrial use so far as known to me, though it is sometimes used to determine whether a given coal can be coked, and once during the last boom in the iron business it is said to have been used for a short time to secure a supply of coke for a furnace which could not get one otherwise, but the broad statement that the process is not in industrial use stands.

Second, *gas retorts*. One process of supplying illuminating gas for cities consists in distilling a high volatile coal in airtight retorts with external heat. The coke is purely a by-product and is used in part for heating the retorts and in part for domestic and other non-metallurgical uses.

Its quality is very poor, being soft and friable owing in part to the kind of coal from which it is made and in part to the process of manufacture; for this reason it is not used in blast furnaces at all, its interest comes from the fact that the gas retort was one of the progenitors of the by-product oven.

Third, *bee-hive ovens*. These now produce about 75% of all the coke made in this country, and are, therefore, of vast commercial importance.

They consist of a bee-hive shaped structure of firebrick generally from 9 to 13 feet in diameter approximately hemispherical in shape. They have a floor of fire brick, a doorway about 30" wide by 36" high, in one side, at the bottom and a charging hole and smoke outlet combined in the center of the dome known as the "eye." These ovens are always built in batteries and frequently in double batteries with the doors in one row on the opposite side to those in the other. The space between them is filled with dirt level with their tops and a track runs over the top of each row to carry a "larry car" which delivers the coal to them. In the case of a double battery the track may be between the rows and the larry have a spout on each side to deliver the coal to either row desired.

The track for the larry is in good practice, always supported on brick pillars coming up from below the base of the ovens so as to eliminate the jar of the passage of the larry cars from the oven proper, as the life of the latter is seriously curtailed when it gets this continual pounding.

In operation the floor and walls of the oven are heated by maintaining a fire on the floor for several days. Then coal which will fill the oven to about 50 per cent. of its capacity is charged through the "eye" in the dome; and leveled off. The doorway has previously been built up with brick and clay almost to the spring of its arch which prevents the coal from running out. After the coal is leveled off, the rest of the door is built in the same manner; airtight except that two or three draft holes are left.

In a short time the heat of the oven begins to distill off the volatile matter which ignites and burns in the free space in the dome. This further heats up the coal and causes more volatile matter to distill off and burn in its turn. The whole mass becomes heated and fuses together in a plastic condition, its temperature being a dull red. The gas from the lower portion of the coal forces its way out through the plastic mass with the result that its structure is cellular to a high degree. John Fulton in his work on coke estimates that good cokes have a cell-space of about 45 per cent. of their total volume.

As a result of the decreasing combustion when the gas evolution diminishes, the temperature begins to fall and the mass of coke develops vertical cracks.

The process is not finished until the volatile matter is reduced to 1 or 2 per cent. As the amount of volatile matter coming off diminishes by degrees, the supply of air through the draft holes is cut off so that it may be, as nearly as possible, only as much as is needed for the combustion of this gas without leaving any air free to attack the coke itself. The air supply is then shut off altogether and after a few hours a spray-pipe is introduced through the top of the doorway and the surface of the coke thoroughly watered down. As little air as possible is admitted during this operation so as to

prevent loss of coke by combustion. After the oven is watered down the brick door is removed and the coke pulled out with hooks, rakes and other appropriate tools on to the platform in front of the oven where the watering-down process is further carried on if any of the coke is hot enough to require it.

As soon as possible after the oven is empty the brick door is reset and the oven charged again. This time the heat of the floor and walls of the oven is sufficient to ignite the coal in a short time without any preliminary firing.

The process is then carried on continuously, charging and drawing as rapidly as possible, because after the oven gets too cold it will not ignite the incoming charge of coal at all, or if the charge becomes ignited more of it has to be burned to waste to make up the heat lost by the oven by radiation while standing idle. The work of drawing is laborious and very hot. For this reason oven pullers are among the most difficult of labor forces to keep in regular supply in an industrial organization.

On account of the severity of the labor it is not customary to draw ovens on Sunday and this, with the necessity for having an oven charged immediately after drawing, necessitates two periods of burning. These are commonly 48 and 72 hours. This is regulated in large part by the size of the charge and in part by the supply of air admitted for combustion. The yield of coke in percentage of the coal charge is larger in good practice with 72-hour coke than with 48-hour, but the yield of coke per oven per day is considerably smaller with 72-hour than with 48-hour coke.

The coke made in the two periods differs to some extent in its physical characteristics. Seventy-two-hour coke is considered harder and, therefore, more desirable for foundry purposes.

The operation of coke ovens on this plan is so simple that it can be done by almost anyone, but in order to get the best results much skill and careful oversight are required. It is not impossible by superior management to increase the yield of coke per ton of a given coal from 60 per cent to 70 per cent of the coal charged in the same ovens. The matter of drafting is particularly important and a large percentage of the coke in the front of the oven may be burned up by improper draft.

It is considered by some coke-oven authorities very objectionable for all the air to be admitted at the relatively low elevation of the top of the doorway and all in one place because, owing to the delay of the air in becoming thoroughly mixed with the volatile matter as the latter distills, the air has an opportunity to attack the coke.

Owing to these considerations ovens have been built with an annular passage around the dome above the level of the doorway, this passage communicating with the oven proper by narrow radial slits in the brick work around the circumference of the oven and communicating with the outside air through a draft door. There is little doubt that better results can be secured with this construction if proper attention be paid to it, but the annular passage is likely to become filled with dirt and the narrow ports stopped up. These are difficult to clean out and when this is neglected the oven is no better than the plain oven which costs rather less. With first-class supervision the annular air-passage is probably a valuable feature, but where the operation of the ovens is left to careless and untrained men its benefit would be short-lived.

The volatile matter which distills off from the coal contains a considerable quantity of tar and during the operation this breaks up at the surface of the mass of coke, presumably, owing to the intensity of the radiation in that region, depositing fixed carbon of a beautiful silver-like luster on the face of the coke. If the watering-down is done without admission of much air, this will be cooled below its ignition point before air reaches it and the coke when drawn from the oven will have the silver luster by which its quality has been so widely judged in the past and is even yet to a considerable extent.

Fourth, *by-product ovens*. Even with best practice there is considerable loss of fixed carbon in coking in beehive ovens.

Moreover the coal contains valuable by-products, especially tar and ammonia, which cannot be recovered in ordinary practice with the beehive oven. Also, the heat-value of the volatile matter is much in excess of that required for the coking operation. This is plainly indicated by the considerable flame rising from the "eye" of every oven in operation.

In the distillation of coal in gas retorts and its coking in coke ovens we have exactly the same fundamental operation carried on for two different purposes and for two different products. In the case of the retort the gas is the desired product, the ammonia and tar are recovered from it and sold. The coke is of little value.

In the beehive oven, on the other hand, the gas is distilled off from the coal much as in the retort, but the gas itself is thrown away or burned up, as are its valuable contents of tar and ammonia, the coke itself being the only product.

It was natural that in the course of industrial development attempts should be made to consolidate these two processes and to make simultaneously coke for metallurgical purposes and gas useful for heating and lighting, with the recovery of tar and ammonia. Such attempts began in Europe more than 50 years ago and owing to the greater cost of coal was the lower cost of technical supervision and labor the result. Resulting from these attempts have almost completely supplanted the beehive oven. In America the opposite conditions prevailing, beehive coke still constitutes three-fourths of the total output, but the by-product oven is making rapid strides and it is only a question of time when it will have displaced the beehive oven as completely as it has done in Europe.

In its essentials the modern *by-product* or *retort-oven* consists of a firebrick chamber about 18 inches wide, 6 feet high and 18 feet long, with flues on each side in which gas and air are burned. The ends are closed by metal doors lined with brick set against metal frames built into the brickwork of the oven. Instead of one opening for charging in the top there are three or more, and instead of the laborious operation of drawing by hand the finished charge is pushed out of the oven by a mechanically actuated ram carrying a sort of rectangular piston of the same general shape as the oven, but somewhat smaller. This is so powerful that it forces the whole mass of coke out at the opposite end of the oven.

There it is caught in a suitable grating or rack, and quenched with a heavy shower of water as quickly as possible. But no matter how quickly this may be done it has had access to the air and enough combustion results to destroy the silver luster, characteristics of good beehive coke. This makes the coke look black and lusterless. For this reason furnacemen in the past have frequently been prejudiced against it and in fact it was a matter of years before the builders of by-product ovens were able to produce coke of metallurgical quality equal to the best beehive. But that point has now undoubtedly been reached.

By-product ovens are built in long batteries parallel to one another and only separated by the air and gas flues on each side. The modified "larry" for delivering the coal to them runs overhead as in the beehive oven, but in handling the gas a vast difference exists. No air whatever is admitted to the ovens, the greatest pains being taken to preserve them absolutely air-tight. The gas is taken off through pipes which deliver to a common gas main, and all the gas is sent to a central purification plant where the tar and ammonia are removed and a portion of the gas is then returned to supply the heat needed for the coking process. The rest of the gas is available for either city lighting or industrial purposes.

In order to maintain the high temperature necessary to force the heat for coking through the firebrick walls of the ovens regenerators are commonly used to preheat the air for combustion and where regenerators are not used recuperators are substituted for them. The results obtained with these latter are not so economical of gas as those obtainable with the regenerators and the best practice tends more and more strongly to the use of the regenerator oven.

These regenerators are commonly built as the substructure

of the oven itself. Sometimes each oven has its own separate regenerator, and in other cases the regenerators are common to a whole battery of ovens.

The first two types of ovens to achieve commercial success in America were the Semet-Solvay and the Otto-Hoffman. The former designed uses horizontal flues, the latter vertical. In more recent years the Koppers oven or ovens of which it is the prototype have taken the lead over the other two. These have vertical flues like the Otto Hoffman oven of an earlier date, which they have largely replaced.

The yield of coke with the by-product oven is always higher than with the beehive. In fact the quantity of fixed carbon in the coke is greater in good practice than the fixed carbon in the original coal.

This apparent paradox comes from the fact that during the operation the tar and volatile matter of the coal are broken up by heat as described for the beehive oven, but unlike the latter the by-product oven does not permit the combustion of any appreciable fraction of the coke produced. The consequence is that the fixed carbon of the coal is augmented by the fixed carbon resulting from the breaking up of the bituminous matter without any loss through combustion.

A wider range of coals can be successfully coked in the by-product oven than in the beehive, though, on the other hand, some coals that can be successfully coked in the beehive oven swell to such a vast extent during the distillation of their volatile matter that it is impossible to push them from the by-product oven. These, however, are few in number.

Much attention has been paid to the best percentage of volatile matter for coking purposes in by-product ovens and its line of commercial development has been very different from that of the beehive oven. The latter has very generally been built as close to the mouth of the coal mine as possible with the object of avoiding transportation charges to the point of consumption of the volatile portions of the coal, and, as the yield from such ovens is relatively small, this is an important consideration.

With the by-product oven, on the other hand, the yield of coke is very much larger and moreover the gas is of great value, as above mentioned. In addition to this the by-product oven will do its best work on coal of a certain content of volatile matter approximately 25 per cent. This is naturally not always found in nature.

The volatile matter in coking coal covers a wide range. It is only from 18 to 20 per cent in the excellent coals of the New River and Pocahontas field and as high as 40 per cent in some other coals. The coal of the Connellsville district contains from 27 to 30 per cent.

In order to secure the advantage of coal the nearest possible to the exact composition desired, recourse is often had to mixtures of different varieties of coals. Mixtures of two are common and mixtures of three or more are sometimes used. Such mixtures enable the best results to be obtained in yield and quality of coke, in quantity of gas and reduction of coking time.

The advantage of making mixtures operates in the same direction as the value of the gas and the yield of coke in making it very desirable to place the ovens at the point of consumption of the coke rather than at the mouth of the mine. These considerations are so powerful that by-product ovens are almost always so located.

Coke as a Furnace Fuel

Coke has many of the most desirable characteristics for a blast-furnace fuel. Well-made coke from good coals is always in large lumps thereby supplying one of the fundamental requirements of a blast-furnace fuel. It has sufficient strength to resist breaking during the necessary handling which it undergoes both while it is being charged and during its descent through the furnace. It has a highly cellular structure which exposes the largest possible amount of surface per unit of weight. Consequently a very large amount of coke may be burned in a given area per unit of time, one of the necessities for rapid operation and high output of furnace.

The tarry constituents in the volatile matter of the original coal are completely destroyed by the coking operation, and there is, therefore, no tar to fill up the interstices in the charge and cut off the passage of the gases of combustion.

The worst objection to coke as a furnace fuel is its sulphur content. This varies from 0.6 per cent in the very best coke up to 2 per cent or more in inferior cokes. But when this limit is much exceeded the fuel ceases to be suitable for the blast-furnace no matter how desirable it may be in other respects. In ordinary good cokes the sulphur will vary from 0.8 to 1.5 per cent.

The second objection is its content of ash derived from the original coal; this varies from about 6 per cent in extraordinarily pure cokes to 18 or 20 per cent in poorer ones. Ordinary furnace fuels range in ash from 8 to 12 per cent.

Phosphorus is ordinarily low, generally under 0.05 per cent, but its amount is important because it all goes into the iron and 0.03 per cent is the maximum amount allowed in some special grades of iron. As some phosphorus is always present in the ore and some in the flux the amount in the coke is of great importance in such cases.

The sulphur can be removed to a very large extent by proper use of fluxes, but the melting of the slag resulting from the use of these fluxes requires more coke and therefore increases the cost of iron made from high-sulphur fuel. Similarly the ash which generally consists in large parts of silica has to be fluxed and this is objectionable for the same reason.

It is, of course, obvious that the more ash the less fixed carbon and the fixed carbon is the only useful component of the coke. This ranges from 80 to 92 per cent, but good furnace cokes ordinarily contain from 85 to 90 per cent of fixed carbon.

Charcoal

It is an interesting fact that the development of the manufacture of charcoal has been along a similar line to that of coke there being three principal methods. Pits or meillers, beehived shaped ovens (ordinarily called kilns when used for charcoal), and retorts. There is no equivalent in the case of wood for the process in which distillation is performed for gas only and the resulting charcoal practically disregarded, as in the case of coal.

Charcoal is in general made from cord-wood, trunks and limbs of trees cut 4 feet long and in good practice when more than 10 inches in diameter, split down to a size equivalent to an 8-inch stick. There are two general classes of woods recognized in charcoal manufacture known as "hard" and "soft." The principal hard woods are hickory, hard maple, beech, yellow birch and several varieties of oak, while the soft woods embrace principally the resinous woods, very commonly the yellow pine and allied species.

The production of soft-wood charcoal is smaller and less important than that of hard-wood charcoal and the value of the coal produced therefrom is less for furnace purposes, it being lighter and softer.

Pits.—In the production of charcoal by this method a space of ground about 30 feet in diameter is leveled off and on this wood is stacked up on end in the form of a truncated cone two lengths or 8 feet high, leaving a chimney through the center. The entire structure is then covered with earth and leaves and fired at the bottom of the chimney. A supply of air is admitted insufficient for complete combustion. The volatile matter is distilled off and burns, supplying the heat to keep the operation going. This continues for a week or ten days, when the wood is all charred and the process completed except the cooling off of the charcoal by standing covered.

There is, of course, some loss of charcoal through excessive air supply and as a result the yield of charcoal per cord of wood in this process is poor, nor is there any recovery of by-products. As a consequence of these disadvantages this process has gone out of use almost completely.

Kilns.—These constitute the next step in the development of charcoal production. They are built of red brick because only low temperatures are needed for the charring of wood and

are very much larger than coke ovens, about 30 feet in diameter at the bottom tapering to about 24 feet at a height of 18 to 20 feet, the whole covered with a flat dome rising about 6 feet further. They are provided with three rows of draft holes at regular intervals, one immediately at the bottom, one about 3 feet higher, and the third about 3 feet above the second. An opening through one side of the dome, about 5 feet square, is provided through which they are charged, and a door about 5 feet wide and 6 feet high at the bottom through which the charcoal is removed, also an opening at the bottom on one side which communicates by a short chimney with a smoke main. They are also provided with a small hole about one foot in diameter in the center of the dome.

These kilns are filled with wood to the top, the wood being piled as uniformly and smoothly as possible with a stack up through the center. Fire is started at the base of the stack and the large top and side openings are then closed with thin steel plate doors and luted air-tight. The fire is permitted to burn very slowly with natural draft through the hole in the top of the dome for a few hours. This opening is then closed and the kiln is connected with the smoke main, on which suction is maintained by a system of fans. The draft is carefully regulated, the bottom row of holes being used first and the higher ones later in the operation. At the end of about 10 days most of the volatile matter is distilled off, then the kiln is disconnected from the main, the draft holes are sealed up airtight and the kiln is allowed to stand for a period of 10 to 20 days in order to cool the charcoal well below the ignition point.

Charcoal is extremely inflammable. It will ignite spontaneously even at atmospheric temperature under certain conditions; presumably, on account of its very great power of absorbing gases, the action would seem to be not unlike that of spongy platinum in igniting hydrogen.

The situation is further complicated by the fact that the use of water to extinguish fires in this fuel is highly objectionable. Charcoal absorbs vast quantities of water which appear not to be driven off except at a very high temperature so that the charcoal seems to descend almost to the hearth of the furnace still containing water and the effect of such water is exactly the same as if introduced at the tuyeres.

On this account charcoal must be cooled with great thoroughness before exposure to the air.

After the coal has been properly cooled all the doors are opened and the buggies which are to deliver the charcoal to the furnace are taken into the kiln and there loaded.

The shrinkage during the charring operation is very great, about 50 per cent. so that while the kilns are filled with wood they are only about half full of charcoal when opened.

The smoke drawn off through the mains by the fans as above described is subjected to cooling and scrubbing whereby its volatile constituents are removed and recovered, but in a very dilute condition because of the great quantity of water vapor in the smoke which comes from the water of the wood, because thoroughly seasoned wood contains about 50 per cent water. Of the other 50 per cent about one-half is charcoal and one-half volatile matter. Unseasoned wood contains much more water than this.

The valuable by-products in the case of wood are methyl alcohol, acetic acid, and wood tar. The latter is not so valuable industrially as coal tar and for that reason is commonly used only as a fuel to aid in the distillation process. The wood alcohol is obtained, first, in the form of a 2½ per cent solution. This is rectified by distillation up to 95 per cent or more. It is perfectly possible to make it chemically pure by proper distillation and a little chemical treatment.

The acetic acid cannot be recovered by distillation because its boiling point is too close to that of water and the two substances dissolve one another thoroughly in all proportions. The acetic acid is therefore recovered by neutralizing it with a mineral base, commonly lime, which forms a soluble but non-volatile acetate. This is recovered by evaporation of the water.

The Retort Charcoal Process.—This process is very similar

to the by-product coking process, but on account of the lower temperature the retort is built of steel instead of fire brick. It consists of a steel chamber, roughly, 6 feet wide by 8 feet high and 50 feet long, surrounded with a brick setting and provided with a fire box under each end. A stack is provided to draw the products of combustion from the fire boxes around the retort. These retorts are charged with eight cords of wood on four-wheel trucks built of steel slats. The retort is closed at both ends by air-tight steel doors and is provided with an outlet for the volatile products of distillation.

After charging, the doors at both ends are closed and fires built in the fire-boxes. The gas outlet is connected to a water-cooled condenser and all the volatile products are condensed therein. The non-volatile gases are highly combustible and are led back under the retort to assist in supplying the heat it requires. In about 20 to 24 hours the process is complete, the doors are opened, the trucks containing the charcoal are withdrawn and immediately replaced by others containing a fresh charge of wood. The doors are then closed again and the process repeated.

The trucks containing the charcoal are drawn as rapidly as possible into the coolers which are steel chambers exactly like the retorts in general shape and size, but more lightly constructed and set out of doors so as to get the maximum cooling effect. There are two of these to each retort set in line with it and separated from it and from each other by a short open space. The charcoal is put first into the nearest one and there allowed to cool for twenty-four hours, and at the next drawing of the retort it is moved into the second one, the fresh charge being put into the first cooler.

On account of the rapidity with which charcoal burns on exposure to the air, the transfers, particularly the one from the retort to the first cooler when the charcoal is very hot, are made as quickly as possible and the air-tight doors of the coolers are immediately closed so that no air can reach the charcoal. Even with these precautions and with an additional cooling of 24 hours in open air, fires by spontaneous combustion of the coal are not infrequent.

This process gives much better yields of by-products than the kiln process. The latter in good practice yields four to five gallons of refined methyl alcohol and 85 to 100 pounds of acetate of lime per cord of wood. The retort process yields in good practice nine to ten gallons of refined alcohol and 170 to 220 pounds of acetate of lime.

The reason that this great superiority in the yield of valuable by-products has not forced the introduction of the retort more rapidly is that it suffers under two disadvantages. First the cost of plant per cord of wood carbonized is about three times that of the kiln plant and for large capacity it runs into such a heavy expenditure as to put these plants out of the reach of any but relatively large and wealthy corporations. Second, the maintenance charges of the retorts and plant generally is very heavy, the bottoms are liable to be burned out by a few hours careless firing and the retort as a whole may be warped so as to be worthless without heavy repairs unless it is managed with great skill.

Those who have installed and managed retort plants with skill and intelligent care think that they constitute the only method of wood distillation worthy of consideration, while those who have operated them carelessly and ignorantly declare with equal positiveness that from a commercial point of view they are inferior to kilns, in spite of the much lower yields of the latter, which are undoubtedly very much easier to manage.

The yield of charcoal in the two cases is not very different, about 50 bushels of 20 pounds to the bushel per cord of wood.

It is probable, however, that this comparison is not quite fair to the retort because it can and does drive off the volatile products more thoroughly than the kiln can do without waste of coal by combustion, so that while the weight of charcoal is about the same in two cases the fixed carbon in the retort coal is greater than that of the kiln coal.

This is partly compensated in the opinion of some operators

by the fact that the retort coal is more brittle and therefore breaks up worse in the furnace than the kiln coal. Such personal experience as I have had tends to contradict this view as I have found that better fuel economy was obtained with retort than with kiln coal.

In a large-scale charcoal operation the difficulty of obtaining an adequate and steady supply of cord wood is very great. The yield of cord wood per acre of timber land is from five to ten cords when only the material unsuitable for saw timber is taken and 40 or 50 cords per acre when all the timber is taken. The former condition is the more common and for this reason areas of several square miles must be cut over per year to supply a large charcoal operation. This makes many transportation difficulties.

In the earlier days of the industry small batteries of kilns were built close to the timber supply and the charcoal was shipped from these to the furnace, no attempt being made to recover the by-products. When commercial conditions forced the abandonment of this wasteful procedure the small batteries of kilns in the woods were abandoned and one large central battery was built preferably at the furnace, because the labor of handling the finished charcoal and its consequent breakage were reduced to a minimum, and, what is equally important, the waste gases of the furnace became available to supply steam for the great amount of distillation involved in the recovery of the by-products.

In those cases in which retorts are installed the same considerations hold and such plants are located at sites where timber may be shipped to them by rail from a large territory. Very frequently these also are located at the furnaces which consume their coal, but not necessarily because owing to the greater profit on their by-products they can sell their coal more cheaply than can the kiln plants and can, therefore, deliver it over considerable distances in competition with kilns.

Methyl alcohol is worth at the plant from 25 cents to about 40 cents per gallon, depending on the location and the perfection of the rectification.

Acetate of lime is worth from 2 to 2½ cents per pound at the plant, depending upon the state of the market.

The cost of recovery with properly designed plants is low and therefore the income received from these by-products has a very important commercial bearing on charcoal production. In fact, the charcoal is the real by-product at many of these plants and the furnace is built simply as the most convenient means to consume this fuel.

Charcoal as a Furnace Fuel

Charcoal is almost an ideal furnace fuel. It is nearly free from sulphur, having only a few hundredths of 1 per cent as against approximately 1 per cent in coke and about 1 per cent of ash against about 10 per cent for coke. Moreover, this ash consists very largely of lime and alkalis, so that it supplies a part of the flux required for the gangue of the ore instead of being largely silica and requiring to be fluxed with additional bases as is the case with coke.

Charcoal has a highly porous structure and can therefore be burned at a rapid rate per square foot of hearth area. This fuel, however, is subject to one drawback. It has not quite the physical strength of coke and would perhaps be unable to stand the conditions existing in a large furnace. On the other hand, owing to the difficulties of wood supply above mentioned, charcoal furnaces are always small as compared with coke furnaces, and therefore the necessity of its having to withstand the pressures customary with large furnaces does not arise.

Charcoal has one bad characteristic not widely appreciated. In spite of its low ash (about 1 per cent) its percentage in fixed carbon is very low, only about 60 per cent, or less in kiln coal. The remainder, about 30 per cent, is volatile matter which is not driven off at any heat which it is permissible to use in charcoal distillation. This volatile matter is about one-half hydrogen and of the remainder a large portion consists of gases of high reducing power, methane and CO among the number.

Because of these valuable characteristics, the fuel per ton of iron produced is less with charcoal than with coke. These matters will be more fully discussed in a subsequent article.

Anthracite Coal

Anthracite coal has about the same chemical analysis as good coke for the reason that it is simply bituminous coal whose volatile matter has been distilled off under conditions of heat and pressure arising from the geological movements of the earth's crust. The pressure has closed up the cells as they were formed and anthracite instead of being cellular like coke is in fact the most close grained of any variety of coal. It only occurs in quantities of commercial importance in a small district in eastern Pennsylvania in the United States, though small deposits are known elsewhere, and deposits of much importance occur in Wales in Great Britain.

Owing to its abundance and cheapness in the early days of the industrial development of the United States it was the principal fuel used in the blast furnace until about 1860, when the development of the coking process began to furnish a rival fuel. As the magnetite mines of New Jersey and the limonite mines of eastern Pennsylvania are in close proximity to the anthracite coal fields, a great iron industry was developed based upon these materials.

But the increasing use of anthracite as a domestic fuel enhanced its value, while the development of the blast furnace proved coke to be the better fuel of the two for its purpose. The anthracite iron industry, therefore, declined, and there are only a few small furnaces using this fuel exclusively, though in the eastern Pennsylvania district, where it is cheaper than good coke, a certain amount of it continues to be used in admixture with coke to lower the cost of the fuel charge.

Anthracite as a Furnace Fuel

Anthracite has three disadvantages as a blast-furnace fuel when compared with coke.

First, it is entirely lacking in cellular structure and is simultaneously of much greater density, so that the ratio of surface exposed per unit of weight is only a small fraction of what it is in the case of coke and only a proportionately small amount can be burned per square foot of hearth area. This means that the output of a given furnace is necessarily much smaller when supplied with anthracite fuel than with coke.

Second, it has a tendency to spall or decrepitate under the action of heat. As a consequence of this spalling action the interstices through the fuel which form the principal passageway for the gases are greatly obstructed and the pressure required to drive the gases through the furnace is much increased. Moreover, this spalling seems to produce a tendency to scaffold the furnace, which will be further discussed in a later chapter.

Third, the much greater density of the fuel as compared with coke reduces the volume of the fuel charge very greatly. This increases the density of the charge as a whole and permits a longer time for the passage of the ore through a furnace of given size. But, for the reason already mentioned above this advantage is useless in increasing the output. On the other hand, the increased density of the charge means increased resistance to the blast.

As a consequence of these three conditions anthracite furnaces are characterized by slow driving and small outputs, high pressure, and a strong tendency to become scaffolded and work irregularly. These are the technical conditions, which, joined with the commercial considerations above outlined, have caused the decline of anthracite as a blast-furnace fuel.

Raw Coal

Certain coals, called "bituminous" for lack of a more descriptive name, while they contain a normal amount of volatile matter, are largely free from tarry ingredients. These are known as "dry" bituminous coals. On account of their relative freedom from tarry matter these fuels fall within the fundamental requirements of a blast-furnace fuel and in the past were quite extensively used as such.

But the development of the coke blast furnace has caused a retrogression in the use of this fuel very similar to that in the case of anthracite. In certain districts where these coals may be obtained cheaply and for the production of certain special irons they are still used in admixture with coke. But so far as known to me there are no furnaces now running in the United States on raw coal fuel exclusively.

Raw Coal as a Furnace Fuel

A lack of porosity and the consequent slow rate of combustion of these coals are presumably the principal reasons for the decline in the use of this fuel. Moreover, though these coals are relatively dry they are not entirely free from tarry matter, and as but a small quantity of tar is required to obstruct the passage of the gas, this also has tended to reduce the rate of driving possible with this fuel. Moreover, the tendency for the furnace to scaffold and work irregularly even with a small amount of tarry matter present in these coals is pronounced. Their use is, therefore, generally confined to a district in southern Ohio, where they occur and are applied in admixture with coke to the production of an iron containing 15 to 20 per cent of silicon and known as ferrosilicon.

The characteristics of these fuels have modified furnace practice, and this in turn has modified equipment and product, so that the classification of iron by the fuels used in their production is fully justified. But as will be seen from what has already been said the only units in the classification which have preserved their individuality unchanged are coke and charcoal, the only two varieties of iron now in common commercial use.

Additional Requirements

We have given a definition of the fundamental requirements of the blast furnace. To these may be added two more, which are necessities in the case of more than 99 per cent of the iron produced.

First, the slag must be sufficiently fusible to run freely from the hearth at a temperature easily attainable.

Second, the blast must be warmed before being delivered to the furnace.

The single exception to these two conditions occurs in the case of furnaces making cold-blast charcoal iron of which probably not over twenty or twenty-five thousand tons per year are produced out of a total of some thirty-five million tons in the United States. In this case the temperature attainable is very low and in consequence the slag is not heated hot enough to run freely and has to be removed from the furnace with the assistance of mechanical means such as slag-hooks, etc., or, if it comes from the furnace without assistance, it chills before going more than a few feet and is accordingly troublesome to remove.

Leaving out of account this very small percentage, all blast furnaces are blown with blast heated from 500 deg. to 1400 deg. F. and their slag is heated to a degree sufficient to enable it to run from the furnace without assistance and far enough to reach some convenient means of ultimate disposal. The heated blast was introduced by the Englishman, Neilson, about 100 years ago, and it has made possible the modern development of the blast-furnace because the velocity of combustion of the fuel is so greatly augmented by preheating the blast, and the continuity of the operation has so increased by raising the molten iron and slag well above their fusion points, that outputs have been increased almost a hundred fold since.

The iron blast furnace is now probably the largest industrial apparatus in use, not only in size of plant, but in the quantity of raw materials consumed and output. Furnaces have often been built which produced 600 tons of iron per day, but modern practice tends to slightly smaller units, furnaces now being built only for an output of about 500 tons per day; but this is maintained as an average output for months and years together.

To produce a ton of iron under favorable conditions requires about 2 tons of ore, $\frac{1}{2}$ ton of flux, 1 ton of fuel and about 4 tons of blast; greater quantities are required when the con-

ditions are less favorable. With each ton of iron is also produced about 6 tons of waste gases and about 1 ton of slag, this, as well as the iron, being handled in the liquid condition. For a 500-ton furnace we have, therefore, to handle every twenty-four hours about 1700 tons of solids, 750 tons of white-hot liquid and 5000 tons of hot gases (blast and waste gases together).

To do this on an industrial scale and with a labor cost amounting in good practice to less than 75 cents per ton a great plant is necessary. Such a plant must contain the following parts: First: The shaft furnace itself through which the entire mass of material just mentioned passes, the solids passing down to the liquid condition at the bottom and the gases upward through them. Second: Means for handling the raw materials, ore, fuel, flux, proportioning them properly and delivering them in certain accurate and positive relations into the top of the furnace. Third: Means for raising the atmospheric air to a pressure sufficient to force it through the furnace in the quantity desired. Fourth: Means for heating this supply of air uniformly and regularly to the temperature desired. Fifth: Means for handling the molten iron on its discharge from the furnace and turning it into a commercially salable product. Sixth: Means for removing the slag from the vicinity of the furnace. Seventh: Means for removing the gases from the top of the furnace and (as these gases are a valuable fuel) for leading them to those portions of the plant where they can supply the energy for compressing the blast and heating it. There is an eighth requirement not embodied in our fundamental definition, but which has become an absolute necessity notwithstanding; a supply of water for cooling certain parts of the furnace and preventing the intense heat inside from destroying the structure.

Available Alkali in Lime

The South African Engineering Standards Committee, supported by six South African scientific and engineering societies, has just published Pamphlet No. 3 of its Chemical Sub-committee, entitled: "Lime, Standardization of Methods of Sampling and Determination of Available Alkalinity" (Price 1s. net, South African Engineering Standards Committee, P. O. Box 1176, Johannesburg, S. Africa).

The pamphlet deals with the uses of lime in the manufacture, transport, and handling, describes methods of sampling unslaked lump lime, crushed lime, and slaked lime, and finally gives the following standard method for the determinations of "available alkalinity" (CaO).

"The sample as delivered for analysis is contained in an air-tight vessel, having been passed through a 30-mesh sieve. It is crushed with a Wedgwood mortar and pestle and the whole passed through a 60-mesh sieve, this operation being performed as quickly as possible. It is then placed in a clean, dry, wide-mouthed bottle fitted with a tight fitting dry glass stopper so as to prevent any access of air. Two grams of this are carefully weighed out and agitated with 1 liter of a 2 per cent cane sugar solution (or 1 gram with $\frac{1}{2}$ liter of 2 per cent sugar solution). If a shaking machine be available, 2 hours' continuous agitation should be given; if not 6 hours' intermittent agitation, every care being taken to prevent coagulation of the lime, in order that the lime and solution may be brought into the most intimate contact during this period. When the agitation is finished the solution is filtered as quickly as possible and aliquot portions titrated with N to or N₂ acid, using rosolic acid as indicator, avoiding delay so as to obviate undue exposure to the atmosphere.

"The distilled water used in the above determination must be made neutral to rosolic acid to counteract the presence of dissolved CO₂."

The metal production of Alaska for 1912 was valued at more than \$22,000,000, divided approximately as follows: Gold, \$17,000,000; silver, \$317,000; copper, \$4,800,000. The development of the coal still awaits a settled policy on the part of the government.

The Radium Institute St. Joachimsthal

By Joh. Hårdén

The medical treatment of diseases by means of radium and radioactive substances has now gained such importance that the great general interest shown both by laymen and scientists seems quite justified. It will be remembered that the Curie's discovered the new element radium in a mineral called pitchblende, which they obtained from St. Joachimsthal about 18 years ago.

During a recent visit to Bohemia the author took the opportunity to visit the quaint old town in the Bohemian mountains, and in the following lines a short report of its important Radium Institute and Factory will be given.

St. Joachimsthal is an ancient township, situated some 20 miles to the northwest of Carlsbad; it was once famous for its silver-bearing mines and smelting works, records of which are in existence as far back as 1515, when the town counted "over 1200 houses" and the smelting works are doubtless still older. By the way, it may be of interest to record, that it is assumed that the name "Thaler" the former German coin-unit has its origin from the silver gained in St. Joachimsthal.

As the mines were exhausted as regards the silver during the following 300 years, the importance of the town as a mining and smelting center diminished; also the war times proved disastrous to the industry, and to-day there are scarcely even ruins of the old silver smelting works left, while the population has dwindled down to only a couple of thousand, barely thriving on lace making, paper box manufacturing, and some revival of mining.

As the yield of silver diminished, the leading men naturally turned their attention to other sources of income from the minerals available. This part of Bohemia is remarkable for its great variety in various minerals; so, for instance, at Schlaggenwald, in about equal distance southwest from Carlsbad, the author found a tin and tungsten mine in full swing on the remainders of an old tin smelting industry and on the old dump heaps a veritable treasure for the geological student was in open daylight. The chemist stated that no less than 95 different minerals, more or less interesting, could be gathered here. Indeed, a large railway viaduct, built from the material taken from the old dump heap, showed a curious admixture of colors, copper pyrites, turmalin, small amethyst and garnet crystals appeared on the fracture of the hewn stone.

In the year 1853, the chemist Paterna, appointed by the Government to investigate the possibilities of St. Joachimsthal, succeeded in finding a practical method for the manufacture of uranium dyes, an industry which proved very remunerative; for instance, in 1886 the factory sold over 11,000 kilograms of these dyes for about half a million marks.

The element uranium was, according to records, discovered by Klaproth in the year 1789 and the metal itself was isolated by Peligot, 1840, both from the uranium-pitchblende from St. Joachimsthal. This mineral consists in the main of uranium oxyduloxyd, together with quartz, iron, cobalt, lead, bismuth, arsenic, calcium, magnesium, copper, vanadium, selenium, and in particular the radioactive substances "radium," polonium and actinium.

The discovery of these radioactive elements by Mr. and Mrs. Curie, in the laboratory of Professor Becquerel in Paris in 1896 is too well known to be further described here. The author had the privilege of being present when the late Professor Curie held his lecture on his far-reaching discovery, assisted by his skilled wife, Madame Curie, on the occasion of their receiving in joint the Nobel Prize in Stockholm in 1905, and it is safe to say that the unostentatious lecture, accompanied by a number of startling experiments, showing the apparent miracle of the birth of a new element, made a lasting impression upon those present.

Mr. and Mrs. Curie had, upon request of Professor Becquerel, commenced the investigation of radioactivity of uranium salts derived from Joachimsthal, and as they soon found that a new and unknown element was present, they obtained a larger

quantity of the slimes remaining from the manufacture of these salts. In this they found a more considerable source of the costly substances, and this slime is even to-day the chief raw material for the recovery of the radium.

The isolation of the new element is rather simple in principle, being a process of dissolving and repeated fractional crystallization, until, at least in Joachimsthal, the pure radium carbonate remains, which is subsequently transformed into bromide or chloride as the demand calls for. But the practical side of the problem is less simple, inasmuch as the element is so rare, that several tons of radium-bearing slimes must be treated in order to extract only a few milligrams, and this, of course, makes the process rather costly.

In addition to the radium salts are also the radioactive waters to be counted. These waters contain the so-called emanation, which is assumed to be a disintegration substance of radium and as such is found to be highly radioactive.

A unit for the radioactivity has been agreed on by the scientists, similar to the units for electric potential, the volt, and the ampere for the current. The unit for radioactivity is called "Mache" after Prof. Heinrich Mache in Vienna, who together with S. Meyer carried out important work on this subject. They soon found that some kind of unit was necessary, and recommended the use of the units of the "Absolute" or the "C. G. S." system. This unit is represented by the strength of the saturation current, which is caused to pass through by the emanation arising from one liter of the water to be tested; it is expressed in electrostatic units. As this, however, would give a too low figure for practical use, it is multiplied by 1000 or 10^3 , and it is this quantity which is generally called "One Mache."

To give an idea of the strength of radium emanation in various springs, counted in Mache units per liter of water, the following table may serve as a comparison:

St. Joachimsthal.....	600 units.
Gastein	54 to 155 units.
Baden-Baden	24 to 126 "
Bath (uncertain).....	20 to 86 "
Carlsbad	1.4 to 50.2 "
Muenster St.....	13.5 to 23.4 "
Teplitz	3 to 8.7 "

These waters are either used internally, or chiefly, as baths, according to the prescription of the doctors. It is, of course, outside the scope of this report to enter into a description of the various cases of which these curative waters of high strength are prescribed; may it be sufficient to mention that very excellent results have been obtained in cases of nervous breakdowns, ischiatic, etc., while the direct application of radium, as well known, is rendering important relief in cases of cancer, ulcers, etc.

The active waters at St. Joachimsthal are conducted direct from the mine, at great depths, into the curehouse, so as to render their curative action as soon as possible to the place of application.

The waters may also be stored and sent to distant places in suitable vessels; it should be borne in mind, however, that the emanation is gradually giving out when so stored, the waters losing their strength at the rate of one-half in 3½ days and this goes on regularly, so that a water containing originally 600 units, has only a strength of 300 after 3½ days, 150 units after 7½ days, 75 units after about 11 days and so forth.

The emanation substance itself is a material of greatest interest physically: it appears in form of a gas which may be isolated and weighed; it is soluble in water, and is capable of passing through porous and gaseous substances. It is also constantly developing energy in form of heat, in fact, one kilogram (2.2 lbs.) of emanation is capable of developing 20,000 horse powers in one hour, if the whole of its energy could be spent accordingly. It may be condensed to a liquid at low temperatures, about 150° C, which shows all the characteristics of the gas. The spectrum is very distinct, though the gas itself is not visible, and non-inflammable. Boiling drives it out of its solution, also shaking, or if a current of air is driven through,

Glass and gems are slightly colored by the action of the emanation, water is slowly decomposed into hydrogen and oxygen, photograph plates are darkened; if strongly concentrated, it is observed to glow in the dark and to render other substances phosphorescent, it also ionizes the air, so as to conduct electricity. It is inert against practically all chemical reactions.

The emanation was discovered through its property of sending off "alpha" rays, the first range of rays given off by radium itself. It seems that the emanation is an instable substance, which as it is emanating the alpha rays, is disintegrating into a substance of lower atomic weight. The precipitate, which is accumulating with somewhat greater velocity on bodies charged with negative electricity, is again an instable substance, which is in its turn deteriorating, thereby giving off both alpha, beta and gamma rays. A product of this substance, called radium D has been specially studied by Dr. Gudzent and found to be of great importance for the medical treatment of some diseases.

Apart from this, the emanation is also splitting up into the gas helium, a well-known element, and this seems to be the lowest step of disintegration.

This gas was discovered by Jansen and Loker (according to Rutherford) in the sun's spectrum, in the year 1868. Nearly 30 years passed before this gas was identified as an earth element, and then it was only found occluded in uranium-bearing minerals, a coincidence which was rather puzzling, as the connection between uranium, radium and helium was at that time unknown; to-day, however, we understand quite well that the disintegration of the radium present in these uranium and thorium minerals had most likely been the source of the occluded helium. R. J. Moos found, when pitchblende residues from St. Joachimsthal were pulverized and treated in vacuum at high temperature, that 1.17% of helium could be extracted.

The emanation, however, is found in smaller or greater quantities, practically all over the earth, since radium is present almost everywhere, though in minimal quantities. But only a few places can boast of such riches in radioactive materials as St. Joachimsthal; the only other source of importance in Europe is the Trenwith mine at St. Ives, Cornwall, where considerable quantities of radium are mined daily, for subsequent purification for the Radium Institute in London.

Reports are reaching us from time to time claiming discoveries of new deposits both in the United States and in Australia; but to the author's knowledge, the bulk of the world's supply of this valuable agent for fighting disease is still prepared from the minerals from St. Ives and St. Joachimsthal. The daily papers are just now mentioning a project, according to which the rich mines at St. Joachimsthal are to be bought up by an English concern, for the stated sum of £700,000. This price may appear high, at a first glance, but if we consider the extraordinarily high price of the radium, amounting to many pounds sterling per milligram (the prices fluctuating with the market) caused by the rarity of the substance and the tedious labor of extracting it from the ores, one wagonload of crude ore only yielding a few milligrams of radium, it is easier to understand why the price should be so high.

The radium factory at St. Joachimsthal is only a small one, compared with the world's demand, but it is no doubt capable of considerable developments, similar to those of the British Radium Institute; given time and means of carrying out all modern improvements.

Luton, England.

JOH. HÄRDÉN.

The Engineers' Society of Western Pennsylvania has organized a metallurgical and mining section, the membership including chiefly the metallurgists of steel mills and allied industries in the Pittsburgh district and mining engineers throughout the Western Pennsylvania, West Virginia, and Ohio coal mining districts. At the first meeting of the section Mr. B. G. Klugh lectured on sintering processes for iron-bearing materials. Besides the metallurgical and mining section, the Society has a mechanical and a structural section.

The Art of Enameling or the Coating of Steel and Iron with Glass*

By Raymond F. Nailler

Before considering the technology of any particular type of enamel it will be well to consider the meaning conveyed by the word enamel. If the present-day enamel be briefly and scientifically designated as a borosodium-potassium-aluminum silicate generally colored by metallic oxides, then the following definition given by Popelin deserves to be quoted since this, notwithstanding its length, may be described as most clear and comprehensive: "Enamel is a glass fusible at a low temperature and usually compounded of borates and silicates. This mixture, originally colorless, combines with the greatest ease with metallic oxides under the influence of a pyrotechnic operation, thereby acquiring various colors according to the nature of the oxide which the enameler can vary at will."

The uses to which the general class of ceramic compounds known as enamel is put are varied. We have noted that enamels are used for artistic or decorative purposes. Parallel to this use we may classify a far more important type of enamels as "commercial," and it is with this type of enamel that we are to concern ourselves.

The first class of commercial enamels is that used on cast iron, and this classification includes the field of sanitary equipment, together with various forms of cast-iron kettles and similar pieces of engineering apparatus.

The enameling of sheet steel may be taken as the second class of commercial enamels. The most familiar division of this class includes cooking-ware enamels. The various forms of so-called agate and granite ware as well as the single colors are made by enameling sheet-steel forms.

The second class of steel enameling which has more recently come into industrial importance is the manufacture of enamel signs, and the third field includes the manufacture of heavy equipment for large-scale food preparation, the dairy industries and general chemical operations. The operations in this last case may take the form of tanks, kettles, evaporators, pipes, etc.

In outlining the technology of the enameling industries as a whole we may include to a certain extent all of the above commercial classes, certain details of which are varied to meet the conditions of cast-iron and various types of sheet-steel products. The outline following, however, is characteristic of all classes.

The first step to be considered is the preparation of the enamel. The purity of the raw materials to be used in the compounding of an enamel must be certain, and in the cases where materials can vary in strength the actual analysis of the substance must be known to assure proper results. In many cases the secret of an enamel lies in its formula and so the compounding of the batches is very carefully guarded, only a person of responsibility having charge of weighing the ingredients. The various materials are generally kept in bins which are numbered, the person in charge of the mixing having the formula stated in terms of these numbers. The properly weighed batch is thoroughly mixed, this being accomplished either by shoveling carefully on a specially prepared floor or by mechanical mixing by means of a rotating agitator.

The product of the mixing room is taken to the smelter in which the various ingredients are fused together in the form of a mass having the characteristics of glass. The furnace in which this operation takes place is a special reverberatory furnace similar to that used in the puddling process in the manufacture of wrought iron. The coal is placed on a grate at the front end of the furnace and the burning gases pass over the bridge wall, strike the roof, and are deflected against the batch. The first change which may be noted in the smelter is the driving off of the water from the borax which produces a swelling up of the mixture. The fluxing materials then melt down and as the heating is continued, dissolve the

*Extracts from a paper published in the October issue of the *Journal of the American Society of Mechanical Engineers*. With the exception of the historical introduction the paper is here given practically in full.

more refractory constituents. If the batch is properly stirred and the temperature of the furnace carefully regulated, the product of this operation is a clear transparent glass containing no particles of unfused material. When a test of the fusion comes up to this standard the furnace is tapped and as the liquid glass flows into a tank of cold water it is broken up by the chilling action of the water, the result being a thorough granulation of the product. The material thus prepared is known as "frit."

The next step in the preparation of the enamel involves grinding the frit to a fineness at which it can be applied to the surface of the metal. The mill here used is the ordinary pebble mill lined with porcelain brick and containing very hard flint pebbles. In the cast-iron industry two general processes are used, the dry and the wet, in sheet-steel work only the wet. In the first case the frit is ground dry, the pulverized enamel being sprinkled on the hot cast-iron piece. In the wet process a certain percentage of pure white clay is placed in the mill with the frit and a certain definite amount of distilled water. When certain grades of enamel are to be manufactured various compounds are also added here to aid in producing desired colors, gloss and opacity. An instance of this is the addition of tin oxide in the mill in the production of white cooking utensil enamels. The fineness to which the enamel is ground depends upon the particular use to which it is to be put, manner of application and other factors. In the wet process the essential feature is that it be fine enough to remain suspended in the water assisted by the clay and the so-called "vehicles" mentioned below.

At this point we may well take up the consideration of the construction and preparation of the material to which the enamel is to be applied. Cast-iron enamels are applied to castings of the desired shape. In the case of cooking ware enamels the shapes are constructed by pressing and spinning. For heavier equipment such as jacketed kettles the apparatus is constructed by riveting or, preferably, welding the sheet steel in the desired form. The selection of the steel with a view to its chemical analysis is of prime importance. A reliable specification reads as follows:

Sulphur	below	0.040
Phosphorous	below	0.030
Manganese	about	0.40
Silicon	about	0.010
Carbon	about	0.10

The steel must necessarily be free from laminations or other mechanical imperfections.

With reference to the construction of heavy apparatus the sheet ranges from 3/16 inch to 3/4 inch in thickness. Two general methods of construction are in use: The first involves the formation of unit sections fitted with flanges. These sections are enameled separately, bolted together at the flanges and the desired apparatus so constructed. The preferable practice, however, is to construct the apparatus in one piece by means of autogenous welding, thus avoiding the use of gaskets or other packing materials in erection.

That the enamel may properly adhere to the surface of the metal the latter must be free from dirt or scale, and in the case of welded joints the welds must have a preliminary grinding to reduce the roughness. The entire surface of the apparatus is then cleaned by pickling or sand blasting, the latter process being altogether used in cleaning large apparatus. As the crude ware leaves the sand blast it has a roughened, clean, metallic surface and is in the proper condition to receive the enamel.

Before applying the enamel to the metallic surface it is prepared by a process known as "setting up." This involves the addition of certain chemicals to the enamel as taken from the mill the function of this addition being to assist the clay in holding the enamel particles in suspension. Substances so added are termed "vehicles." At this state the enamel must be diluted with distilled water to the proper consistency for application.

In applying the enamel to the metallic surface three general methods are in use: The first, applicable to small pieces only, is known as "dipping," the piece being dipped into the enamel, the excess of which is shaken off, leaving a thin coating on the metal. The second method, known as "slushing," involves pouring the prepared enamel over the surface and allowing it to drain. The third method, which is the principal one used on larger apparatus, involves spraying the finely ground enamel on the metallic surface by means of the compressed air atomizer.

Preliminary to the consideration of firing the enamel we may well review the types of furnaces in use. The first type is known as the muffle furnace and involves the use of a large fire clay oven externally heated by means of coal, gas or other fuel. The apparatus to be fired is placed on suitable supports in this muffle. The other type of furnace is known as the direct fire furnace, in which the heat from the fire is taken up by the walls of the firing chamber and radiated to the apparatus placed within the chamber on suitable racks. This general class of furnace has two special divisions in that, on the one hand, the piece is rotated within the furnace, while on the other hand, the piece is allowed to remain stationary. For small work the muffle is in general use, but for the production of large apparatus the direct-fire furnace is necessary. At first thought, the muffle furnace may be considered to have an advantage in that the products of combustion together with the dust from the fire cannot come in contact with the enamel. Again it may seem that a more even heat can be realized in the muffle. On the other hand, with a properly designed direct-fire furnace in which the combustion is complete before the gases reach the firing chamber no trouble is experienced, due to their presence or to the dust from the fire. The use of natural gas further does away with this latter possibility.

In a furnace for firing smaller ware the charging mechanism is a fairly simple matter, it being necessary merely to place the material in the furnace by means of a small fork operated by hand or mechanically. But in the manufacture of engineering apparatus where a single piece may weigh 3000 to 4000 pounds, it is necessary to have a large mechanical charging machine on which the piece may be placed outside the furnace, the arm of the machine then properly placing it in the furnace. The general design of such a machine suggests the charger used in open-hearth practice. The apparatus to which the enamel has been properly applied is placed in the furnace, which is maintained at the proper temperature. This temperature varies with the nature of the enamel and in cases of high-silicon acid-proof enamels reaches in the neighborhood of 2500 deg. F. The control of the burning is made possible by the changes which occur in appearance of the enameled surface as fusion takes place. At first the fine particles of enamel begin to fuse together and a general blister condition exists, giving the surface a very dull appearance. But as the enamel matures this dull appearance gives way to a bright glass, which, when properly developed over the inside surface, is indication that the piece should be withdrawn from the furnace. The time required to burn a piece properly depends upon the temperature of furnace, thickness of metal, and nature of enamel.

Nothing has been said so far as to the composition of the enamel or of the number of coats applied. In general there are two kinds of enamel, known as ground coats and cover coats. The former serves as a bond between the enamel and the steel, and the latter serves to build up the body of the enamel and presents the finished surface.

In the ground coat color is no object. Its composition is such as to render it adherent and strong. In addition to the ordinary components cobalt oxide seems to be essential to the production of adherence. The explanation of this is debatable.

The cover coat is the one which forms the major part of the enamel and if definite color, opacity, etc., are objects, the necessary ingredients for their production are introduced here, assisted by mill additions as noted above.

In the manufacture of acid-proof enamel the cover coat is essentially a high silicate and must be free from any metallic oxides, such as oxide of tin, lead, iron, etc.

The piece to be enamelled receives one ground coat which is burnt well into the steel at a high temperature. The cover coats may be one or two in number for ordinary enameling, but should be at least triple for acid-proof work. In the production of acid-proof apparatus the use of a ground coat or cover coat is now eliminated and the same material is employed for both which in place of being an enamel, as commonly termed, is in reality a boro-silicon glass and without the use of any metallic oxides in its compounding.

It is very interesting to note the chemical changes which take place in the various stages of the production of the finished enamel. Avoiding as far as possible deep technicality, they may be summed up as below. As a starting point, let us select a cover coat formula used in the production of a "dark blue" cooking ware enamel.

Feldspar, lb.	120	Salt peter, lb.	7
Quartz, lb.	72	Oxide of Cobalt, lb.	7 1/2
Borax, lb.	80	Oxide of Manganese, lb.	1
Cryolite, lb.	30	Clay in the mill, per cent.	1

First considering the behavior of each of the constituents when heated we can later clearly note the general reactions which take place when they are fused together in the smelter.

Feldspar varies greatly in composition but as commonly used in enamels is an aluminium-sodium-potassium silicate of approximately the following analysis:

	Per Cent
Silica (SiO ₂)	70
Alumina (Al ₂ O ₃)	17
Soda (Na ₂ O)	7
Potash (K ₂ O)	6

On smelting, none of these constituents vaporize, so we may consider them all later in the smelting of the above enamel.

Quartz introduced as a pure glass sand contains practically 100 per cent silica (SiO₂).

Borax is chemically known as sodium tetra-borate, and in the crystalline form as used has a certain definite amount of so-called water of crystallization which must be taken into account. The formula Na₂B₄O₇·10H₂O is resolved into Na₂O·2B₂O₃·10H₂O. Without going through the calculations assume this to correspond approximately to the following analysis:

	Per Cent
Water (H ₂ O)	16.0
Boric Oxide (B ₂ O ₃)	37.0
Soda (Na ₂ O)	47.0

Of these the last two do not vaporize on smelting, but the water is evaporated, hence 100 lb. of borax smelts to 84 lb. of the remaining oxides.

Cryolite is a double fluoride of sodium and aluminium, the formula of which may be written Na₃AlF₆. When smelted the sodium and aluminium appear as oxides and from 100 lb. of cryolite we realize about 24 lb. of alumina (Al₂O₃), 44 lb. of soda (Na₂O) and 54 lb. of fluorine (F₂). There is some dispute as to whether or not the fluorine is vaporized. In the present discussion it matters not, hence we shall consider that the third of these three compounds is lost in smelting.

Salt peter is potassium nitrate KNO₃. When heated under the conditions of smelting it may be considered to break up into potash (K₂O) and nitrogen pentoxide (N₂O₅). The reaction is $2KNO_3 = K_2O + N_2O_5$. By calculations based on this reaction 100 lb. of salt peter yields about 47 lb. of potash (K₂O) and 53 lb. of nitrogen oxide (N₂O₅). The latter may be considered as completely vaporized.

Oxide of cobalt (CoO) may be taken as non-volatile and pure. The same may be assumed for the oxide of manganese (MnO₂).

To sum up the above as an outline of the reactions taking place in the smelter

120 lb. Feldspar gives $120 \times 0.70 = 84.0$ lb. Silica (SiO₂)

		120 × 0.17 = 20.4 lb. Alumina (Al ₂ O ₃)
		120 × 0.07 = 8.4 lb. Soda (Na ₂ O)
		120 × 0.06 = 7.2 lb. Potash (K ₂ O)
72 lb. Quartz	gives	72 × 1.00 = 72.0 lb. Silica (SiO ₂)
80 lb. Borax	gives	80 × 0.19 = 15.2 lb. Water (H ₂ O) (Vaporized)
		80 × 0.37 = 29.6 lb. Boric Oxide (B ₂ O ₃)
		80 × 0.47 = 37.6 lb. Soda (Na ₂ O)
30 lb. Cryolite	gives	30 × 0.44 = 13.2 lb. Soda (Na ₂ O)
		30 × 0.24 = 7.2 lb. Alumina (Al ₂ O ₃)
		30 × 0.54 = 16.2 lb. Fluorine (F ₂) (Vaporized)
7 lb. Salt peter	gives	7 × 0.47 = 3.3 lb. Potash (K ₂ O)
		7 × 0.53 = 3.7 lb. Nitrogen Oxide (N ₂ O ₅) (Vaporized)
7 1/2 lb. Cobalt Oxide		
	gives	7 1/2 × 1.00 = 7 1/2 lb. Cobalt Oxide (CoO)
1 lb. Manganese Oxide	gives	1 × 1.00 = 1 lb. Manganese Oxide (MnO ₂)

We shall consider that of the above the H₂O, N₂O₅ and F₂ are vaporized. This leaves for the constituents of the frit (totals of the above)

	Lb.	Per Cent
Silica (SiO ₂)	159	53.5
Alumina (Al ₂ O ₃)	27.6	7.5
Soda (Na ₂ O)	59.2	20.3
Potash (K ₂ O)	10.5	3.6
Boric Oxide (B ₂ O ₃)	29.6	10.2
Cobalt Oxide (CoO)	7.5	2.6
Manganese Oxide (MnO ₂)	1	.3

Total 291.4

The loss, theoretically, on smelting is plainly $317.5 - 291.4 = 26.1$

26.1 lb. or $\frac{26.1}{317.5} = 8.2$ per cent. (317.5 lb. original weight of batch).

The mill additions together with the agents used in "setting up" are fused with the frit as the piece is fired. By a process similar to the above we could compute the final composition of the enamel by taking these additions into consideration. The actual amount of material added in this case, however, is so slight and of such a nature that the change resulting therefrom is not sufficient to affect materially the composition of the enamel. When an addition of about 12 per cent tin oxide accompanies the clay a very significant change in the composition of the enamel is produced.

It may be well to note in passing some of the means by which various colors are produced in the enameling industries. It will be impossible to enter into great detail without taking too much time, but the mention of certain compounds in connection with the colors produced by their use will serve our purpose.

The production of a good white enamel either for casting or sheet-steel work may be said to depend, at the present time, upon the use of tin oxide. Great have been the efforts to substitute less expensive substances, such as compounds of antimony and lead. But an antimony white which looks good alone is plainly seen to be off-color when compared with a good tin oxide white.

Going to the other extreme of color, black, we encounter difficulties. There is any number of formulae for black enamels, but when the results are closely compared we find that the colors range widely through brown blacks, blue blacks, purple blacks, etc. Certain compounds of manganese and iron used together give a color approaching black. Other formulae call for the combined use of oxides of manganese, cobalt and copper. Again we find oxide of nickel added to the above three oxides.

A color much seen in enamels is blue and the use of cobalt is very satisfactory in the production of this color in various

grades of intensity. Manganese alone produces purples and violets, and in combination with cobalt gives various shades of purple-blue.

Green enamels are chiefly produced by the use of chromium oxide and copper oxide, while in some cases a mixture of copper and cobalt oxide is used.

Reds of various shades are produced by the use of red oxide of iron. In connection with it we find that tin oxide aids greatly in giving capacity and bringing out the color. In the production of brown enamels we may use ferrous chromate. Various yellows are produced by salts of cadmium, chromium, and uranium.

The more delicate shades of rose and purple are produced by the use of gold compounds. So-called "pink rose" is used in the manufacture of certain artistic enamels. Perhaps the best known gold compound used in enamel coloring is "purple of Cassius." The exact composition of this product is a question. It is made by the combined use of auric, stannous, and stannic chlorides. The color produced is also commonly called "purple of Cassius."

Before drawing this paper to a close, attention is invited to a general consideration of the future of the enameling industry. Neglecting art enameling and sign making we come to the field of steel enamels. So far as the cooking ware industry is concerned, the field is practically constant. Granting that the demand for that class of article is increasing, as the public becomes accustomed and educated to its use, there is an opposing tendency in the rapidly increasing use of aluminium ware. Exactly how these and other factors now balance would be difficult to ascertain. But aluminium is a metal and its metallic properties cannot be denied. Under certain conditions it is attacked by various substances used in the culinary arts and a contamination of the preparation is inevitable. No doubt the time will come when a high silica enamel known to be free from tin and other poisonous compounds will enter the cooking ware field. The government is becoming more and more careful in protecting the public from foods of injurious nature, and it is not too much to expect that soon it will establish more rigid restrictions relative to the ingredients entering into the manufacture of apparatus in which food is to be prepared. At such a time an enamel coming up to requirement will be free from injurious compounds and will come into great demand.

In the preparation of foods on a factory scale we find an enormous and constantly increasing demand for larger pieces of enameled steel apparatus in the form of pans, kettles, tanks, pipe, etc. There are many lines of pressure being brought to bear both by the government and public opinion which lead to the conclusion that the increasing demand for this style of apparatus is without limit. Canning and preserving factories and dairy establishments have found a large use for copper and tin in the construction of containers, vacuum pans, etc. The acids of fruit juices and vegetable pulps have a very marked action on these metals and the resulting contamination of the product is known to be of danger to the consumer. The use of an enamel containing tin, lead or other metallic oxides is but the first step in the right direction. The presence of these metallic oxides in the enamel renders it corrodible and contamination results. The solution is the use of an acid-proof enamel free from all such poisonous substances. In the milk industry a similar line of reasoning applies. Further compare the ease of maintaining sanitary conditions in a one-piece enamel-lined unit with the trouble experienced in the use of a metal container or even an enameled article made up of composite parts between which are gaskets.

Another consideration relates to the preparation of chemicals later used in food products, for instance, baking powder. Many operations connected with the manufacture of such products have been carried on in lead or other metallic pans and the resulting contamination has given no end of trouble. Acid-proof enamel is rapidly solving this problem also.

Finally consider the chemical manufacturing processes now carried on in apparatus of lead, wood and earthenware, neces-

sitated by the corrosive actions of the liquors and gases involved. This includes the pharmaceutical field which alone is a matter of great importance. In all these and many other lines the use of acid-proof enameled apparatus is rapidly finding and filling a great demand.

Not only does steel apparatus meet the demands of modern industries, but in case a cheaper product is desired and at the same time a heavier construction is permissible, acid-proof cast-iron apparatus has its field. The possibility for size and variety of construction is, of course, more limited than in the case of sheet-steel apparatus.

In view of these considerations and many others which these have called to mind, we cannot but conclude that the use of enameled apparatus has just begun and with this extension of the long known art of metal enameling, a field of great industrial possibilities both for manufacturer and user has been opened. We may not be criticised as being over optimistic when we predict that in their ultimate stage of development the enamel industries will be ranked among the greatest of commercial activities. At such a degree of development the enameling industry will in no way deserve classification among the lost arts.

The Glucose and Starch Industry in the United States

Final statistics of the manufacture of glucose and starch in the United States for 1909 are given in detail in a bulletin soon to be issued by Director Harris of the Bureau of the Census, Department of Commerce. It was prepared under the direction of W. M. Steuart, chief statistician for manufactures.

Of the 118 establishments canvassed in 1909, 93.2 per cent were engaged primarily in the manufacture of starch, but the value of products of these establishments formed only 32.5 per cent. of the total value of products reported for the combined industry. The eight establishments engaged primarily in the manufacture of glucose formed only 6.8 per cent of the total number of establishments, but the value of their products represented 67.5 per cent. of the total value of products for the industry.

The establishments in the industry as a whole in 1909 gave employment to an average of 5,827 persons, of whom 4,773 were wage earners, and paid \$4,079,722 in salaries and wages.

The capital invested amounted to \$38,866,410. The cost of materials used in the industry as a whole in 1909 was \$36,898,771, and the total value of products was \$48,790,311.

A striking feature of the industry, as indicated by the figures, lies in the fact that while the number of establishments was less in 1909 than in 1879, the value of products was more than four times as large, thus showing a greatly increased productive power for the average establishment.

As measured by the value of products, Illinois was the most important state in the industry in 1909, followed by Iowa, New Jersey and Indiana, in the order named. In the five-year period, 1904-1909, there was an increase of only two per cent. in the number of wage earners employed in the industry. On the other hand, the value of products increased 49.5 per cent. in five years. The wide discrepancy between the relative advance in value of products and in number of wage earners employed is doubtless indicative of improved processes used in manufacturing the products.

The average number of persons engaged in the glucose and starch industry during 1909 was 5,827, of whom 4,773, or 81.9 per cent., were wage earners. Nearly all the wage earners (98.1 per cent.) reported for the industry as a whole were employed in establishments where the prevailing hours of labor were sixty or more per week.

Form of Ownership

In 1909 of the total number of establishments 46.6 per cent. were under corporate ownership, as compared with 40.7 per cent. in 1904. In 1909 the value of products of these establishments represented 96.2 per cent. of the total, and in 1904 96.8 per cent.

Eleven per cent. of the establishments in the industry as a whole in 1909 manufactured products valued at \$1,000,000 or over, such establishments returning 89 per cent. of the total value of products, and 18.6 per cent. of the establishments reported products valued at \$100,000 or over, as compared with 15.7 per cent. in 1904. The average value of products per establishment in the industry as a whole increased from \$233,213 in 1904 to \$413,553 in 1909. The average number of wage earners per establishment shows an increase from 33.4 in 1904 to 40.4 in 1909. In the glucose branch of the industry the average value of products per establishment in 1909 was \$4,116,305, and the average number of wage earners 350. In the starch branch of the industry the average value of products was \$144,258, and the average number of wage earners 18.

The total expenses in the glucose and starch industry in 1909 were \$43,973,558, distributed as follows: Cost of materials, \$36,898,771, or 83.9 per cent.; wages, \$2,606,483, or 6.1 per cent.; salaries, \$1,413,239, or 3.2 per cent., and miscellaneous expenses, made up of advertising, ordinary repairs of buildings and machinery, insurance, traveling expenses and other sundry expenses, \$2,995,065, or 6.8 per cent. The unusually high proportion of the total expenses formed by cost of materials and the low proportion formed by wages is explained by the fact that the various processes in this industry are almost entirely mechanical.

Materials and Products

There was an absolute increase of \$16,149,475, or a relative increase of 49.5 per cent., from 1904 to 1909 in the total value of products for the industry as a whole, which was \$48,799,316. Corn and potatoes are the most important materials used in the manufacture of glucose and starch. Computed on the basis of 50 pounds to the bushel, the 2,240,508,915 pounds of corn used in 1909 was equivalent to 40,009,088 bushels. Computed on the basis of 60 pounds to the bushel, the 210,608,127 pounds of potatoes used was equivalent to 3,510,135 bushels. Wheat flour is also an important material in the industry. The quantity and cost of arrow root and other roots used as material are combined with that of wheat, the total for these materials in 1909 amounting to 1,940,000 pounds, valued at \$21,435.

Glucose (including glucose syrups) is the most important product when measured by value. The value of this product as reported for 1909 was \$17,922,514, or 36.7 per cent. of the total value of products for the combined industry. The increase in the value of glucose from 1904 to 1909 amounted to \$5,509,898, or 45.1 per cent. Glucose was manufactured in only four states—Illinois, Indiana, Iowa and New Jersey. Corn oil, a product obtained chiefly in the process of manufacturing glucose, increased in value \$1,638,302, or 140.7 per cent. The increase in the value of stock feed amounted to \$1,567,480, or 35.3 per cent.

A total of 677,535,047 pounds of starch of all kinds, valued at \$17,514,823, was manufactured in the United States in 1909, as compared with 356,695,335 pounds, valued at \$10,027,538 produced in 1904. The production of corn starch increased 327,684,552 pounds, or 105.3 per cent., in quantity, and \$7,084,466 or 79.8 per cent in value in the five-year period. This large increase was due entirely to increased domestic consumption. Starch made from wheat and roots decreased 4,008,255 pounds or 22.5 per cent in quantity, and \$395,724, or 35.2 per cent, in value in the five years.

The quantity of potato starch decreased from 27,700,400 pounds in 1904 to 24,873,415 pounds in 1909, or 10.2 per cent., while the value decreased \$101,457, or 11 per cent. Potato starch was manufactured in 1909 in Colorado, Maine, Minnesota and Wisconsin, but the principal point of activity was Aroostook County, Maine, where 61 factories reported the consumption of 171,283,746 pounds, or 81.3 per cent. of the total of 210,608,127 pounds of potatoes used in the United States in the manufacture of starch, and the manufacture of 20,514,277 pounds, or 82.5 per cent. of the total quantity of potato starch reported for the industry. Starch products are used for food, for laundering and sizing, for finishing calico, for thickening colors, and for many other purposes.

Investigations of Blast Furnace Operations*

In a paper before the May 4, 1913, convention of the Verein Deutscher Eisenhüttenleute, Prof. W. Mathesius, of Berlin, developed a method of analyzing blast-furnace operations. The method was then applied to records obtained from twenty-eight different blast furnaces, and charts were drawn that show at a glance the interrelations of the most important factors in blast-furnace practice. Following the theoretical analyses, the results of experiments upon the relative reducibility of briquetted, sintered, and unroasted ores, were given.

In developing the method of analysis, it was assumed that all reactions between the charge and the gases except four could be discarded. These four reactions are as follows:

1—The oxidation of the carbon in the coke, in the hearth by the blast to carbon monoxide.

2—The reduction of iron oxides by the carbon monoxide which takes place in the middle regions of the furnace.

3—The reduction of carbon dioxide by the carbon in the coke. The former may come either from the charge or be generated by a reaction between carbon monoxide and ferric oxide. This reaction can take place only at temperatures considerably above the well-known Boudouard limit of stability: that is, at least as high as 900° or 1000° C. The equation is:

4—The catalytic dissociation of carbon monoxide which takes place in the uppermost regions of the furnace

This last reaction can only take place when the substances are considerably above the previously mentioned stability conditions, both as to quantity and temperature; that is, the temperature must be from 400° to 600° C. Above 600° C. the speed of the reaction becomes so slow that it has little practical bearing upon the blast-furnace operation.

Of the four reactions mentioned above, the first, second and fourth are useful, while the third is detrimental to the economic working of the furnace.

Reaction 4 is favorable to economical operation on account of the restoration of carbon that would otherwise be lost and works in direct opposition to the harmful reaction 3. In considering the performance of the furnace as a whole, reactions 3 and 4 can be assumed under favorable conditions to compensate each other and, therefore, in analyzing the performance of a blast furnace, reaction 4 can be left out of consideration entirely, while reaction 3 is only considered under conditions where it is not completely compensated.

It is possible for reaction 4 to become harmful under certain unfavorable conditions; for instance, if it takes place to an abnormal degree, the amount of carbon dust may become so great that it seriously increases the resistance of the charge to the passage of the gases.

Below we give the equations used in the mathematical analyses of data received from the various furnaces:

LIST OF SYMBOLS

$m = \frac{(CO_2)_g}{(CO)_g}$ = the weight ratio of the carbon dioxide to carbon monoxide in the waste gases.

$m' = \frac{(CO_2)_a}{(CO)_a}$ = the volume ratio of carbon dioxide to carbon monoxide in the waste gases.

Further, in kg. per kg. of pig iron,

C = the total carbon from the coke.

C_x = the carbon of the coke consumed by harmful reactions (the dissociation of CO_2 in the shaft and the reduction of Fe_2O_3 in the hearth which in this analysis are considered as identical because they produce the same effects upon the consumption of coke and the heat performance of the furnace).

C_{cz} = the carbon in the CO_2 of the ore and the flux

C_{ci} = the carbon taken up by the iron.

*Translated in abstract from Stahl und Eisen, Sept. 4 and 11, 1913

C_{mn} , Si, P = the carbon taken up by the reduction of MnO , SiO_2 , P_2O_5 in the hearth.

O_e = the oxygen of the oxide of iron in the ore.

O_l = the oxygen brought by the blast in the hearth.

O_b = oxygen from the charge contained in the waste gases.

$(CO_2)_g$ = the carbon dioxide in the waste gases.

$(CO_2)_{ez}$ = the carbon dioxide of the ores and the flux.

$(CO_2)_d$ = the carbon dioxide formed by reduction of the ore with CO, which is again dissociated by C.

$(CO_2)_y$ = the carbon dioxide formed by reduction of the ore with CO.

$(CO_2)_{ezu}$ = that portion of $(CO_2)_{ez}$ which passes up the shaft intact.

$(CO_2)_{ezx}$ = the $(CO_2)_{ez}$ which is decomposed in the shaft.

$(CO)_g$ = the carbon monoxide in the waste gas.

$(CO)_{fexos}$ = the carbon monoxide produced by the direct reduction of iron ore by C.

The general equations used in the analysis are given in full below:

Carbon Dioxide Equation.—The amount of CO_2 in the waste gases, not including that which comes from the ore mixture and is not reduced by the carbon from the coke in its passage upward, must equal the amount of CO_2 formed from CO by the reduction of ore, less that amount which is again dissociated by the carbon of the coke according to reaction 3.

$$(1) \quad (CO_2)_y - (CO_2)_{ezu} = (CO_2)_y - (CO_2)_d$$

The carbon dioxide of the ore mixture is split up as follows:

$$(2) \quad (CO_2)_{ez} = (CO_2)_{ezu} + (CO_2)_{ezx}$$

Carbon Equation.—The carbon from the coke, less that which has gone over to the iron as carbide and plus that which comes from the ore mixture, must be equal to the amount of carbon present in the carbon dioxide and the carbon monoxide of the waste gases.

$$(3) \quad C - C_{fe} + C_{ez} = 3/7 (CO)_g + 3/11 (CO_2)_g$$

Oxygen Equation.—The oxygen of the ore forms CO_2 with CO in the shaft of the furnace, or CO with C in the hearth.

$$(4) \quad O_e = 4/11 (CO_2)_y + 4/7 (CO)_{fexos}$$

The carbon which enters into the harmful reactions must equal the carbon which is gasified according to $(CO_2)_d + (CO_2)_{ezx}$, together with the carbon which reacts in the hearth forming $(CO)_{fexos}$.

$$(5) \quad C_x = 3/11 [(CO_2)_d + (CO_2)_{ezx}] + 3/7 (CO)_{fexos}$$

The expression $(CO_2)_{ezx}$ may be worked out from equations 1 and 2. Subtracting equation 1 from equation 2, we have by proper transposition:

$$(CO_2)_{ezx} = (CO_2)_{ez} - (CO_2)_g - (CO_2)_l + (CO_2)_y$$

This value when substituted in equation 5 gives:

$$(5^a) \quad C_x = \frac{3}{11} [(CO_2)_{ez} - (CO_2)_g - (CO_2)_l + (CO_2)_y] + \frac{3}{7} (CO)_{fexos}$$

For developing the values $(CO_2)_g$ and $(CO_2)_y$ the equation is written as follows:

$$(5^b) \quad C_x = \frac{3}{11} (CO_2)_{ez} - \frac{3}{11} (CO_2)_g + \frac{3}{11} (CO_2)_y - \frac{3}{7} (CO)_{fexos}$$

For obtaining $\frac{3}{11} (CO_2)_g$ we have from equation 3:

$$C - C_{fe} + C_{ez} = \frac{3}{7} (CO)_g + \frac{3}{11} (CO_2)_g$$

By substituting $(CO)_g = \frac{7}{11} (CO_2)_g$ we find:

$$C - C_{fe} + C_{ez} = \frac{3}{22 \cdot 11} (CO_2)_g (11 + 7m)$$

hence

$$(6) \quad \frac{3}{11} (CO_2)_g = 7m \left(\frac{C - C_{fe} + C_{ez}}{11 + 7m} \right)$$

$\frac{1}{11} (CO)_y$ is worked out from equation 4 thus:

$$O_e = \frac{4}{11} (CO_2)_y + \frac{4}{7} (CO)_{fexos}$$

hence

$$(7) \quad \frac{1}{11} (CO_2)_y = \frac{1}{4} O_e - \frac{1}{7} (CO)_{fexos}$$

Substituting equations 6 and 7 in equation 5^b, we have:

$$(5^c) \quad C_x = \frac{3}{11} (CO_2)_{ez} - \frac{7m}{11 + 7m} (C - C_{fe} + C_{ez}) + \frac{3}{4} O_e$$

According to the molecular ratio $CO_2 = \frac{11}{3} C$, hence

$$\frac{3}{11} (CO_2)_{ez} = C_{ez}$$

This, substituted in equation 5^c, gives:

$$(5^d) \quad C_x = \frac{3}{4} O_e - \frac{7m}{11 + 7m} (C - C_{fe}) + \frac{11}{11 + 7m} C_{ez}$$

It should be noted that the above equations are purely theoretical, and possess a perfectly general applicability, since no assumptions were made to fit any special local conditions.

FIG. 1—DIAGRAM OF BLAST FURNACE OPERATIONS

If the CO_2 and CO are expressed in volumetric percentages instead of weight, the equation 5^d would be written

$$(5^e) \quad C_x = \frac{3}{4} O_e - \frac{1}{1 + 11m} [m' (C - C_{fe}) - C_{ez}]$$

The equation for C_x make it possible, wherever O_e , C_{fe} and C_{ez} are known, to construct a chart which gives a perfectly clear picture of the relations between C , m and C_x in the operation of any blast furnace. By assuming different values for m Fig. 1 has been thus constructed for operation with basic pig iron which has the following average composition:

C	3.70 %
Mn	1.734 %
P	1.713 %
Si	0.41 %
Fe	92.704 %
	100.00 %

Assuming a blast temperature of 600° C., and calculating the heat balance for the process, the total loss through cooling

water and radiation is found to amount to 24.48 per cent of the total heat supplied.

Now, if it is assumed that the loss remain practically constant for different points in the chart, the blast temperature may be inserted as unknown in the heat balance equation and determined for different values of m and C , the results being represented by lines drawn across the first ones.

The completed diagram or chart in Fig. 1 illustrates the intimate connection existing between coke consumption, blast temperature and the ratio of CO_2 to CO in the waste gases. Furthermore, it shows that with a constant blast temperature the changes in furnace operation must take place along that particular temperature line, thus determining the relations between the other variables and plainly indicates the great effect of the m or " CO_2 to CO ratio" upon the coke consumption, because the other variables remain fairly constant.

A cursory examination of this chart reveals the great importance of keeping continuous records of the m ratio in the operation of a blast furnace. The chart further shows that when working at the maximum m ratio (of CO_2 to CO) the lowest coke consumption is reached, and it may be interesting to trace the reason for this effect.

Naturally the amount of CO_2 in the waste gases is higher, the easier the reduction of the ore; that is, the greater the amount of reduction that takes place in the furnace by action of the gases, or conversely the ratio of CO_2 to CO is smaller, the greater the amount of ore which is directly reduced in the hearth by action of the carbon.

The value of the ratio of CO_2 to CO is also dependent in a very marked manner upon the regularity of working and uniformity of the furnace charge which for best conditions should offer a uniform resistance of the passage of the gases, thus making a uniform distribution and flow.

The point A in Fig. 1 indicates the conditions of practical operation in the particular case which was investigated. This furnace was charged with friable ores, and, therefore, had to be driven slowly in order to avoid trouble, which is indicated by a study of the diagram. On the one hand, the CO_2 to CO ratio is extraordinarily high (1.07), while, on the other hand, the carbon C available for compensation of the harmful reaction is relatively small. From these two facts it is evident why, with a yield of only 40 per cent, it is possible to get along with a coke carbon consumption of only 800 kg. per metric ton of iron. The carefully obtained heat balance sheet showed, as mentioned before, a loss of 24.48 per cent in cooling water and radiation.

Realizing that the cooling water and radiation losses for a given temperature vary only slightly for a given kind of iron, whether the operation is conducted fast or slow, it is evident that a furnace of given dimensions and operating conditions which produced double the amount of iron per ton of raw material will have half the cooling water and radiation losses per ton that the same furnace would ordinarily have. Therefore, it follows that blast furnaces should be operated at as high a speed as practicable.

Practical experience in different places, as well as these experiments, have shown that attempts to speed up the furnace operation always lead to the production of white cold pig, and this is true because of the small amount of C carbon available for counteracting the disturbances due to non-uniform settling of a friable charge and to the quantities of ore arriving un-reduced in the hearth of the furnace.

The operation of a furnace under these conditions is extremely difficult because the varying quantities of un-reduced ore which enter the hearth cause large variations in the hearth temperature.

In the case discussed above it appears difficult to determine the best conditions for operation because the furnace must be driven slowly on account of the friable nature of the charge, and this method of operation entails relatively large heat losses, a small coke consumption, and also small amounts of C carbon available for harmful reactions in the hearth.

The possibility of choosing more favorable conditions is

shown in Fig. 2, which is constructed under the assumption that a large portion, especially of the friable portion of the charge, is briquetted. The effect of this, as shown by experience, is to permit a considerable acceleration of the process without introducing irregularities into the working of the furnace and therefore the heat losses are reduced. In Fig. 2, at point B , it is assumed that they amount to 13 per cent. This sets free considerable heat which is available to counteract the harmful reactions. Due to this, the C carbon exceeds 0.14 per kg. of iron, which causes a change in the operating point of the diagram corresponding to a reduction of the CO_2 to CO ratio which goes down to 0.6. This reduction, however, makes it possible to use a hotter blast and thus to bring about a considerable saving of coke, for by raising the blast temperature to 800°C . the operating point may be transferred to C , as shown in Fig. 2.

This method of analysis also shows that increasing the speed

FIG. 2.—DIAGRAM OF BLAST FURNACE RELATIONS

of operation has the beneficial effect of considerably reducing the amount of blast required per ton of iron. In equation (3) the oxygen required for operation was given. If we substitute in this the values $(\text{CO})_0$ and $(\text{CO}_2)_0$, as given in equations (10) and (10), we obtain by simple transposition,

$$O_1 = \frac{4(11 + 14m)}{3(11 + 7h)} (C - C_{Fe} - C_2) - O_0$$

Substituting in this equation the value $m = 0.1$, we have the oxygen required as

$$O_1 = 1.41 (C - C_{Fe} - C_2) - O_0$$

If we substitute $m = 1$ the oxygen required is

$$O_1 = 1.85185 (C - C_{Fe} - C_2) - O_0$$

The ratio for the two cases works out

$$\frac{O_1}{O_2} = \frac{1.41}{1.851} = 0.702$$

In studying the literature of the subject it was found that

widely varying values were assigned to the losses of blast-furnace operation. Indeed, in some cases heat balances were given in which there was more heat on the outgoing side than on the incoming. Consequently, in order to obtain a reliable basis for the assumption for radiation and cooling water losses, it was necessary to calculate a very large number of heat balances for different blast-furnace operating conditions and for this purpose the author obtained suitable data from twenty-eight different furnaces and subjected them to calculations, the results of which are set forth in tabular form. The sum and substance of a careful analysis of these calculations shows that the economy of operation could be greatly increased if the ore could be introduced into the furnace in such a condition as to facilitate its rapid reduction; that is, in briquetted form.

On the other hand, it is very important to note that the total carbon consumption per ton of iron under high-speed operating conditions is not greater than in cases where the operating speed is less and the ratio of CO_2 to CO much more favorable. This is because in furnaces operating at higher speed there is a marked reduction in the radiation losses which offsets a higher coke consumption as compared with the slower furnaces.

In order to obtain a clear idea of the relation between the speed of operation of a furnace and the heat losses a diagram shown in Fig. 3 was developed. In this diagram it was assumed

FIG. 3.—DIAGRAM SHOWING HEAT LOSS BY RADIATION

that the heat losses are inversely proportional to the speed of operation. The points of the diagram were taken from actual calculations. The diagram in Fig. 3 shows that the speeds used in current practice to-day correspond to a loss of approximately 1000 kg. calories per metric ton, and that by speeding up the operation they might be reduced to at least 50 per cent of their present value.

Unfortunately, at present there are only a few cases where briquets have been used for a sufficiently long time under proper conditions of operation to enable the actual saving in fuel to be determined. Consequently, there is not much data from actual practice available.

However, the author was able to present figures obtained in practice by Gustav Gröndal from his experience in Swedish iron works, where by the introduction of briquetted ore he was able in one instance to reduce the charcoal consumption from 1314 kg. per ton to 1000 kg. per ton by using a charge composed of 50 per cent briquets, and in this instance the iron content of the charge was increased from 56 or 57 per cent up to about 62 per cent.

In another case which Mr. Gröndal relates, the charge was made up entirely of briquets, and in this instance the charcoal consumption was only from 560 to 585 kg. per ton of iron.

Such favorable results from the use of briquets in the operation of blast furnaces can only be realized by careful attention to all the conditions that are involved, and operating the fur-

nace in a uniform manner and in such a way that by far the greater portion of the charge is reduced to metal by the gases.

Exhaustive experiments bearing upon the reduction of iron oxides by gases have been conducted at the Technische Hochschule in Charlottenburg, and the detailed results of these investigations will form the subject of a special thesis. However, the nature of the results is plainly shown in the accompanying diagrams.

In these experiments the briquets were tested in quantities of a few hundred grams, each broken into pieces of about nut size. These were heated to different temperatures in an electric furnace and subjected to the action of a stream of illuminating gas for several hours. Under this treatment, depending upon the nature of the briquet, varying amounts of the ore were reduced to metal or ferrous oxide.

The results are shown in Figs. 4 to 18, from which it is seen that briquetting makes it possible to transform practically all of the iron oxides, contained in the ore, into metal. On the other hand, while sintered material must be subjected to the action of the gases for a much longer period, in order to reduce the ferric oxide to metallic iron, the ferrous oxide cannot be reduced by the gases. In some cases the ferric oxide in the sintered ore was only partially reduced to metal, while the rest was transformed to ferrous oxide.

It is noteworthy that the briquetted material gave more favorable results than the lump ore, the cause of which probably lies in the physical structure of the briquet, which, being more porous, is more susceptible to the action of the gases. Figs. 8 and 18 demonstrate this very plainly. Fig. 8 represents a piece of solid magnetite, while in Fig. 18 the same ore was pulverized and briquetted by the Scoria process.

These results show the great importance of using briquetted material in blast furnace operations. By substituting briquets for friable ores, and ores which are difficult to reduce, such as magnetite, it is possible to operate a given furnace at a considerable higher speed, thus increasing its daily capacity and decreasing the percentage losses in cooling water and radiations, the result of which is a considerable saving in coke.

* * *

In discussing Professor Mathesius's paper, Professor Simmersbach, of Breslau, made the following remarks:

The results of Professor Mathesius's investigations show that sintered ores are not well adapted to indirect reduction. I fully agree with his conclusions, yet it is nothing new. About ten years ago I brought out these same facts in connection with studies made by me upon sintered iron ore containing manganese. It was shown that with the same manganese content in the sintered ore charge there was less manganese reduced and entering the iron and that for a certain percentage of manganese in the iron additional manganese had to be added to the burden, which naturally caused an increase in coke consumption.

The speaker cannot agree with Professor Mathesius in his assumption that reactions (3) and (4) may be considered as practically offsetting one another. Theoretically this might be permissible, but practically considered, both of these reactions must be taken into account. According to the first reaction, CO_2 is taken from the carbon of the coke, while in the second one carbon is returned; however, not to the coke, but to the ore. The effect of this absorption is to cause the ore to swell, become more porous and thus increase its reductibility by the gases, and this is most important in indirect reduction. According to tests made by Laudig at Buffalo, the carbon absorption by the different ores is as follows:

Mesabi ores		21.61 per cent of the ore weight
Soft hematite ores		13.82 per cent of the ore weight
Hard hematite ores		7.52 per cent of the ore weight
Hard crystalline hematite ores		3.68 per cent of the ore weight
Iron slags		0.38 per cent of the ore weight
Magnetites		0.00 per cent of the ore weight

In absorbing this amount of carbon the Mesabi ores swelled to double their normal size and became very much more porous. I have here a piece of magnetite taken out of the hearth

of a blast furnace, which 2 mm. below its surface is still in its original unaltered condition. This incomplete reduction is due to the density of the magnetite.

In the mathematical analysis of blast furnace operations as to the deposition of carbon, it must be borne in mind that the burning of coke according to reaction (4) produces 50 per cent more heat than direct burning; this is demonstrated in the following calculations based on furnace gas containing 1 CO₂ to 2.25 CO.

(a) Direct Burning. (C + O = CO and CO + O = CO ₂).	
1C develops by burning to CO ₂	8080 heat units
2.25C develops by burning to CO	5557.5 heat units
3.25C develops by burning.....	13637.5 heat units
1C develops by burning.....	4196.5 heat units
(b) According to Reaction (4).	
(C + O) = CO and 2CO = CO ₂ + C).	
2C develops by burning to 2 CO	4940 heat units
2CO = CO ₂ + C	
1CO develops by burning to CO ₂	5610 heat units
1CO absorbs by the reduction to C...	2470 heat units
	—
	3140 heat units
1C gives according to direct burning.	4196 heat units
2C develops	12276 heat units
1C develops	6138 heat units

Pb	1.21
Cu	0.51
Al ₂ O ₃	0.84
CaO	0.91
MgO	0.94
Sulphur as sulphide	2.27
P	0.114

The balance mostly oxygen.

In the briquetting of flue dust a number of important factors are to be considered, namely, the variable chemical composition, the quantities of raw, sintered and melted particles composing the dust and also the coke fines therein contained. The age of the dust and the place from which it was obtained is also important, as fresh dust always contains hydraulic binders. If left for any length of time in the open or in flues distant from the furnace, subjected to the influence of moisture or carbon dioxide, the binding constituents will become hydrates and carbonates. Dr. Schumacher first discovered the practical significance of the last named phenomenon, and thereby developed his briquetting process.

When briquets are tried out on the furnace, it is customary to replace a certain amount of ore by as large a quantity of briquets as possible. If there is an improvement in the operation of the furnace, the briquets are credited with the same. If, on the contrary, the operation of the furnace is impaired,

FIGS. 4 TO 18.—REDUCTION OF ORES SINTERED AND BRIQUETTED MATERIAL. FIGS. 4 TO 8.—ORES. FIGS. 9 TO 13.—SINTERED ORES. FIGS. 14 TO 18.—BRIQUETTED ORES AND FLUE DUST

Because of the lack of time, I refrain from further criticism as to the author's method of calculation, since his conclusions have for years been found correct in actual practice.

Referring to the results of experiments as plotted in Figs. 4 to 18, it should be noted that the various processes cannot be compared with each other unless the same raw material is used in all cases. Considering particularly a flue dust briquet and its reducibility the following analysis was obtained from a partly reduced Schumacher briquet containing 25 per cent metallic iron:

Total carbon	7.40
of which coke, graphite.....	4.88
SiO ₂	0.55
Fe	61.00
Mn	0.40
Zn	6.70

it is a question whether this is directly chargeable to briquets, or only indirectly. When using briquets on a furnace the blast is of primary importance, and the pressure, the amount and their temperature must carefully be considered. Although sintered material is more difficult to reduce than briquets, and therefore less advantageous, yet there may be unusual conditions under which sintered ores, with correspondingly high temperatures and certain ore mixtures, will give better results than briquetted material.

In the author's experiments better results were obtained from briquets than from lump ores. A reason for this, besides the difference in density, is due to the coke amounting to from 10 to 25 per cent, and which is distributed evenly in the briquets. It is my opinion that the coke in the briquet should be figured as coke in the calculated charge, as to the coke consumption.

Professor Osann made the following remarks in the discussion:

The author's temperatures used in test are too low to be of greatest practical value, as they do not indicate what takes place in the hottest part of a blast furnace.

Professor Osann takes issue with the author on the point that the most easily reducible ore mixtures are always the most desirable ones. Practice does not, in all cases, bear this out. Ores that are difficult to reduce are often added to the charge in order to improve the performance of a furnace by counteracting certain difficulties that occur when easily reducible ore mixtures are used.

It is well known that ores that are difficult to reduce are very desirable when first-class iron for casting is wanted. The very easily reducible Lake Superior ores are reduced in American furnaces with no less an amount of fuel than are the ore mixtures of the lower Rhine, which are rich in magnetite. The reason of this is that easily reducible ores pass so quickly through the furnace that the saving in fuel is offset.

The blast furnaces in America use at least as much fuel as the furnaces in Germany under similar conditions, and probably the American furnacemen would be well pleased if their ores did not reduce so easily.

It is also well known that in Siegerland and in Steiermark red spar is not used alone but about one-third of raw spar is added. By this means the disturbances caused by the easily reducible ore are practically eliminated.

The cause of these phenomena we do not exactly know at the present time. We do know, however, that in blast furnace operation all the different factors work together and that no one of them can be considered by itself.

As far as deciding which briquetting process should be used, no other way is open except experimentation, and these experiments must be continued over considerable length of time. Professor Osann advises that, without any prejudice, experiment should be conducted with both sintering and briquetting processes and decision should be made entirely in conformity with results obtained.

Some processes should be dropped out at once as being of too little advantage or of too great a cost.

Sinter is often compared with slag because of its resistance to reduction; however, this is not entirely permissible, because slag consists principally of silicates while sintered material is produced by gangue going into solution in iron oxides without the necessary melting.

When flue dust briquets, made by the use of a binder, sink into the furnace, they soon behave in some similar way to sintered material.

Professor Osann recommends a program for exhaustive experiments to prove the value of briquetting and then closes by criticizing the use of temperatures below 900° C. in the tests and the assumption of a constant heat loss in the analysis. He hopes, at some future time, to be able to discuss in detail the effect of speed of operation upon heat losses.

Condenser Tube Corrosion

Past and Future Work of the Corrosion Committee of the British Institute of Metals

By Sir Gerard A. Muntz, Bart., and Professor H. C. H. Carpenter, M.A., Ph.D.

The (British) Institute of Metals Corrosion Committee, which consists of the following members: Sir Gerard A. Muntz, Bart., chairman; Professor H. C. H. Carpenter, M.A., Ph.D., Hon. Secretary; Dr. G. D. Bengough, M.A., Hon. Investigator; Mr. L. Archbutt, Engineer Rear Admiral G. G. Goodwin, R.N.; Professor A. K. Huntington, Assoc. R. S. M.; Mr. J. T. Milton; Mr. A. Philip, B.Sc., Assoc. R.S.M.; Sir W. E. Smith, C.B.; Mr. L. Sumner, M.Sc., and Professor T. Turner, M.Sc., has now been at work for some three and one-half years.

Under its guidance two reports have been published by Dr.

G. D. Bengough, who has carried out his investigations in the Metallurgical Department of the University of Liverpool.

The first report, issued in January, 1911, and published in Vol. V of the *Journal of the Institute of Metals*, was intended to give a general review of the knowledge as to the corrosion of non-ferrous metals both in its practical and scientific aspects, and is the most comprehensive survey of the subject that has yet been published. On the basis of this report the committee decided to initiate an experimental investigation of the cause or causes of the corrosion of condenser tubes in marine engines.

An appeal for funds was issued and the response was sufficient to enable a two years' research to be undertaken, which formed the subject matter of the Second Report to the Committee presented at the Ghent meeting of the Institute of Metals held at the end of August in the present year.

CORROSION RESISTING TUBES

The experimental work has been carried out both in a special condenser and by means of laboratory experiments. The condenser plant was erected with the object of reproducing as accurately as possible the conditions to which condenser tubes are submitted in actual practice, and the laboratory experiments were designed to interpret the observations made with the larger apparatus, a procedure which has been signally successful in its results. In both cases it was found possible to observe and study "dezincification" which is the usual cause of the failure of tubes in practice. Tubes of four different compositions have been examined under strictly comparable conditions. The ordinary 70:30 tube of commerce has been shown to be far surpassed in resistance to dezincification by tubes containing 70 per cent copper, 28 per cent zinc, and 2 per cent lead, and by those of "Admiralty" composition, i.e., containing 70 per cent copper, 29 per cent zinc and 1 per cent tin.

Muntz metal, 61 per cent copper, 39 per cent zinc, has been shown to be unsuitable for use as condenser tube material.

GREAT IMPORTANCE OF TEMPERATURE

The influence of a variety of "deposits" and "particles" which have hitherto been supposed to cause localized dezincification has been shown to be of only secondary importance, and dezincification has been found to start and proceed rapidly in their absence. *In all cases the rapidity of the failure of the tubes was found to depend principally upon the temperature to which they were subjected.* If corrosion is to be prevented, or at any rate minimized as much as possible, *the temperature in the condenser must be kept low.*

Preliminary experiments have been made on the mode of action of electrochemical protection. This has been found to be intimately connected with the deposition of a continuous layer of calcium carbonate upon the inner surface of the tubes.

SCHEME OF NEW YORK

The committee have met recently and having obtained sufficient funds to continue their investigations for another two years they have planned a further scheme of work which is now well in hand. In deciding upon the lines of future investigation they have been careful to take into consideration a number of valuable suggestions and criticisms which have been made on the Second Report both in the discussion at Ghent and in the comments of the technical press. The scheme includes a complete time-temperature survey of the conditions under which dezincification can take place and a more detailed study of the temperatures existing in their own and other condensers. Special attention will also be directed to the conditions under which electrochemical protection can be effectively maintained, and in this connection a comparative study of all the principal methods of holding tubes in tube-plates will be carried out. A systematic series of experiments will also be initiated with a set of tubes of a copper-aluminum alloy from which specially interesting results are anticipated.

The foregoing scheme by no means exhausts the lines of investigation which in the opinion of the committee might profitably be undertaken, and if further financial support is forthcoming they will gladly extend their researches in other equally vital directions.

Sizes of Pipe for Cyanide Mills and Industrial Plants

The accompanying curves will be found useful in determining the size of pipes to be used for water and solution in cyanide mills, or in industrial plants where it is necessary to convey definite volumes of liquid through pipes from one point of a process to another. The present chart was drawn by Mr. Justin H. Haynes, and used by him in the design and construction of the Junta mill, near Telluride, Col. The solid line refers to a velocity of 4 ft. per second, and should be used whenever possible. The dotted line is based on a velocity of 6 ft. per second and is not normally used.

SIZES OF PIPES FOR CYANIDE MILLS AND INDUSTRIAL PLANTS

An acid-proof lining for tanks can be prepared from the following formula: 10 per cent litharge, 20 per cent short-fibre asbestos and 70 per cent sand, mixed to a plaster with a 40° Be. solution of silicate of soda. The plaster can be applied as thick as desired. An application of acid after drying will "set" the cement and render it acid-proof.

Refractories in Montana.—Among the raw materials used by the Anaconda Copper Mining Co. for making refractory brick are (1) a plastic clay from Arrington; (2) a flint clay from Lost creek; (3) silica, and (4) "Dillon" rock. The silica (3) used for silica brick contains about 97 to 98 per cent SiO_2 ; lime is used as a binder. The "Dillon" rock runs 99 per cent SiO_2 , and is used for sanding molds; it is a fine, dense, white sandstone, not fit for making silica brick. Analyses of the two clays are given below.

	Plastic	Flint
SiO_2	55.7%	76.9%
FeO	1.1	0.0
MgO	0.5	0.0

Ozone

By A. Vosmaer, Ph.D.

In ordinary oxygen two atoms are combined to form a molecule, but it takes three atoms to form a molecule of ozone. Different names have been given to this particular gas. Some people have called it activated oxygen, others have given it the name of condensed oxygen, some have spoken of electrified oxygen and the name polymerized oxygen has also been suggested.

None of these suits the purpose in a strict way. It is better to distinguish sharply between substances of different properties. In fact, Ostwald who defines a body as a state of things

differing from its surroundings, considers allotropic modifications as different substances and this seems very sensible. It is really too bad to have different sets of properties for one and the same substance in different modifications, such as red and yellow phosphorus, or diamond, graphite and carbon, or sulfur in all its varieties. Is not it much more plausible to consider them as really different substances?

The fact that chemically they closely resemble each other does not entitle us to consider them as one and the same, it is not only the chemical properties which determine a substance, and even in that respect we are not always so very sure about it.

The names "activated" and "condensed" oxygen are wrong altogether. Ozone is more active than oxygen because one, or all three of its atoms, are holding each other more less firmly than the two in oxygen. The well-known oxygen in *oxygene nascenti* is none the less as active as ozone. One should not lose sight of the fact that if we speak of oxygen we have in mind the gas in its molecular, (two-atomic) state and not in its atomic state. Atoms are altogether different in their behavior from molecules, so we must guard ourselves against mixing them up. This consideration also condemns the word "condensed," because there has been no condensation of O_2 but of O .

The prefixes "electrified" and "polymerized" do not please me

either, the first because it is too vague, the second for the same reason as above, that ozone is no polymerization of oxygen, is not (O_3)¹ but is O_3 .

What other name shall we give it then? Well, if we call it ozone there is no need for another name. Its composition has been fixed to be O_3 its molecular weight being 48.¹

A great difficulty for philosophical consideration is that we know all substances by their molecular state while in chemistry we deal with them in their atomic state. This cannot be altered for the present. It has to be endured as long as it cannot be cured.

MANUFACTURE OF OZONE

Ozone is difficult to make. It is an endothermic compound, which means that it absorbs heat when forming. How much has not been settled yet. The amount seems to be in the neighborhood of 30,000 gram calories per gram molecule. But unfortunately the temperature of formation and that of decomposition lie very close together, so that, although heat is wanted, it should be kept away as well. In other words as soon as the ozone is formed it should be taken out of the heat zone.

Practically this means that ozonators work best at the lowest possible temperature. There is always quite enough heat in the discharge itself for the formation of the ozone and all that is formed must be quickly drawn away, out of the influence of the discharge which also has the tendency to desozone.

These circumstances present interesting cases of equilibrium reactions. When working with air it is hardly possible to get a higher concentration than about 30 grams per cubic meter (containing about 260 grams of oxygen) and this figure does not run up so very much higher when using pure oxygen instead of air.²

Ozone may be made chemically, mechanically, and electrically and in different ways, but most of them have not the slightest importance from a commercial viewpoint.

By way of example we call attention to the chemical method of making oxygen by means of sulfuric acid and permanganate of potassium; oxygen thus made contains some ozone. By way of curiosity we mention the fact that violent mechanical disturbance of the air may cause some very little ozone to be formed. It has been reported that when grinding wheels were being tested for bursting speed and when they were flying to pieces the odor of ozone was noticed.

Among the electrical methods there are two; one in the foreground, one in the background. The latter one is the electrolytic when electrolyzing strongly acidulated water, or rather diluted sulfuric acid (sp. gr. 1.1), the oxygen liberated is strongly ozonized; up to 17% (according to others up to 25%) of the oxygen may be ozone, the process being carried out at low temperature and with a high current density. If we take something like 70 or 80 grams of oxygen per kw-hour, as a practical figure, the yield in ozone comes up to 20 grams under the very best conditions. The yield is low but not so low as to cut out competition, because the other products, oxygen and hydrogen, may have their share in the business and may considerably reduce the cost.

For the present moment, however, the other method, that of electric discharges through air or oxygen is ahead of all other methods on account of the yield being several times that of other methods. Commercial ozonators yield up to 70 or more grams of ozone per kw-hour.

The subject of ozonators is one of importance but is too large to be treated in a few words.

For our purpose it will be best to consider only the very best make. Other systems may have scientific interest, but have no chance of permanent application.

None of the systems in which no solid dielectric is used, has been able to make its way while the system based upon the use of a solid dielectric has succeeded in holding its original position.

The principle underlying is very simple. Any two conductors with sufficiently high potential difference (say above 6,000 volts) and separated by some solid dielectric will discharge the electricity in the form of the so-called dark, silent or brush discharge. This is the kind that possesses the remarkable property of converting oxygen into ozone. Although this principle is simple enough in itself, the details of the method by which it is carried out into actual being, are very important. Numberless patents have been taken out for different arrangements, but, most of them are stone dead and only few are of value.

Those patents are not basic. They all refer to some arrangement, form of electrodes, shape of dielectric and so on. We shall not discuss them here because this article is intended to show the importance of ozone rather than that of some particular make of ozonator.

As said any arrangement of electrodes separated by a dielectric will do. Not all will do equally well. Some apparatus are excellent in the laboratory, others are good in technical work. Some people want ozone of very high concentration, others again want it at least cost. In some cases reliability is of first importance, for instance, when using ozone for the sterilization of drinking water. In other cases high output per kw-hour is the principal requirement. As we intend to devote a future article to ozonators, we shall not enter into details now.

If we compare the theoretical equivalent of ozone in kilowatt-hours with the actual yield, a very great discrepancy is found. We ought to obtain over 1000 grams and at the most we get 100 grams per kw-hour, that is 10 per cent at the very best, and yet there is little hope for further improvement unless some genius strikes a happy thought. For the present moment one has to be content with such low figures as 10 per cent and in most cases not more than 5 per cent efficiency.

PROPERTIES OF OZONE

The pre-eminent property of ozone is its extraordinary oxidizing power, which from a chemical standpoint, can be best judged from the fact that it oxidizes silver.

Popular pamphlets enumerate a great many substances that will be oxidized by ozone, including such substances as ferro compounds, mercury compounds, etc. Now this is not worth mentioning, since if we once know the tendency of ozone to oxidize, it goes without saying that certain reactions will occur. We need not give such a list which anyway could be enlarged to any length.

What is particularly interesting about this property of ozone is that when it has fulfilled its oxidizing function there remains nothing but oxygen, which, being a gas, can easily be got rid of if so desired. This point should be borne in mind when we have to carry out some oxidizing process because in many cases we want to oxidize but do not want any other reactions such as are likely to occur when we use one of the more common oxidizers.

Peroxide of hydrogen has a similar advantage in so far as what is left in its case is water. It is, however, not so easy to get it in a pure state. It does not keep very long unless in acid solution, but it answers the purpose if pure.

We need not insist upon the fact that very few chemical reactions take place when we just drive oxygen gas into some solution. With ozone this is quite different. Here we have oxygen *in statu nascendi* exempt from other chemicals. It will, therefore, prove a very valuable agent in many chemical reactions.

It is disputable whether or not its remarkable bactericidal power is the same as the foregoing, or if it is another property.

If we stop to realize what it means to sterilize water containing thousands and thousands of bacteria per cubic centimeter by using a quantity of one in a million (that is one gram of ozone to sterilize 1,000,000 grams of water or 1 cubic meter or about 260 gallons), we feel inclined to attribute this abnormal power to some definite and specific action on bacteria. As matters are presently I would not dare, however, to claim such a specific property for ozone. It may be just nothing but ordinary oxidation.

¹ Leaving out of consideration, for the present moment the facts that partly it may be of more complicated nature, i. e., partly O_3 , partly O_4 .

² Professor Warburg obtained values of over 200 but on very small laboratory scale.

Ozone is said to cause phosphorescence in water. It may be so, I have never seen it. But I happened to watch another very curious phenomenon which went on for a whole day. But afterwards I have never been able to get it again. This unfortunate circumstance has prevented an explanation or even a suggestion.

On one of the hundreds of days that I have been working with ozone and water, once it happened that the sterilizing apparatus, which was made of glass so as to permit watching the operation, turned a violet color.

The sterilizing apparatus was a glass cylinder, 1 ft. in diameter, and 30 ft. high (built up in sections). During all the particular day the regular appearance of that column was changed to a violet color, about the shade of a faint amethyst or the reflection of arc light on a wet street. Probably the phenomenon has no bearing upon ozone but is merely a physical effect due to an intimate and very finely divided mixture of gas and water. The same color may sometimes be observed at the edge of the water line when going at a good speed in a calm sea.

That much for the chemical properties of ozone. The physical properties are of importance when it comes to the making of ozone. Ozone is a colorless gas with a sharp penetrating odor which has often been compared to that of chlorine or phosphorus. However, chlorine smells absolutely different from ozone, and comparing it with phosphorus means comparing it with itself, since the peculiar smell of phosphorus is probably due to slow combustion which is said to generate ozone. Here again I would rather say that ozone smells like ozone.

The gas is very unstable. It takes very much trouble to have that third atom join the two others and it is a very loose connection. It decomposes slowly at ordinary temperatures, but rapidly at high temperatures. Above 270 deg. C. it cannot exist under ordinary circumstances.

At a pressure of 125 atmospheres and a temperature of minus 103 deg. C. ozone becomes liquefied, it is then a dark blue mobile liquid of notable magnetic susceptibility.

Ozone is an endothermic compound, that is it requires heat for its formation, which, however, does not mean at all that the hotter an ozonator the better. On the contrary, the cooler the better.

The property of being very unstable prevents us from being able to store ozone. We hardly can expect even to be able to sell ozone as a liquid in steel bottles like carbonic acid or so. But there is no need for this, since the market offers many kinds and sizes of ozonators and with them any amount and any concentration can be obtained that may be wanted in the industries.

USES OF OZONE IN DAILY LIFE

The utility of ozone culminates in the purification and sterilization of drinking water. This is a subject of such importance that it is rather difficult to do justice to it while confining the discussion to a few lines, as is necessary in this short article.

It can be done when we are allowed to leave out the proofs of what we are saying. Be it sufficient to say that all statements are based on personal experience, except the experiments with pathogenic bacteria, which have been carried out by the German Imperial Board of Health.

To be very brief, we may just summarize what is known by saying: Ozone when of proper concentration and when judiciously applied will kill any amount of bacteria in water. We tested up to as many as 600,000 per cubic centimeter. Ozone acts selectively in so far as the pathogenic, which are the least resistant, are killed first. The German Board of Health tried mixtures up to 30,000 cholera and as many typhus bacteria, added to ordinary river water and none of those were left after treatment.

Some people do not realize the size and nature of bacteria and feel uneasy about their carcasses, but a little figuring will reassure them.

Suppose some water to contain 100,000 bacteria per cubic

centimeter, which is an abnormally high figure. There are 375,000,000 in a gallon, their size is about .00004 in their cubic size, 0.00000000000004 cubic inch, so that the tremendous number, 375,000,000 bacteria per gallon occupy only 0.00000004 cubic inch for the whole lot. Now consider a bacterium that consists of about 90 per cent of water, and 10 per cent solid matter. A solid may contain something like 0.1 per cent of mineral matter, mineral matter than said 0.000024 cubic inch of bacteria yield 0.0000000024 cubic inch of "ashes." Thus it is evident that there is so little matter in bacteria that it matters little whether or not we take it into consideration. Moreover, one has to remember that water usually contains some mineral matter so that after all the last figure should have been expressed in percentage increase and that shows the absurdity of thinking of remnants or cadavers of bacteria, which moreover are not an animal but of vegetable substance.

There is overwhelming evidence as to the absolute bactericidal power of ozone in water, but one *conditio sine qua non* has to be considered, viz., that of competent planning and expert management. Both conditions have very often been overlooked and failure could not but result.

Besides its bactericidal power, ozone has also that it takes away all discoloration, even that caused by organic ferric compounds (the precipitated iron has to be removed afterward by suitable means). It also takes out any disagreeable smell and taste, giving a taste like fresh spring water, which is probably due to the excess of oxygen.

Everybody who really has had thorough experience with the ozonization of water will have to acknowledge the absolute superiority of ozone as a purifier to any other method. Ozone is the ideal. Nothing more is left to be desired, not even the cost. We may mention here that as 1 gram of ozone can treat 1 cubic meter, or say 250 gallons of water of medium quality, and as one gram ozone of sufficient concentration per cubic meter of air to do the work can be produced by 20 watt-hours, there are required 80 kw for 1,000,000 gallons of water per hour. The cost of this amount of energy *delivered 24 hours a day* is a figure which varies from place to place, but is by no means prohibitive, as is well known to readers of this journal.

We wish particularly to draw attention to this extremely low figure of cost because many people repeat the verdict "too expensive" without even knowing the cost and certainly without realizing the advantages.

Another reason why we mention the price is that, after all, ozone is expensive in itself. It is because so little of it is needed for *this* purpose that the cost comes so low. For many other chemical processes it is out of the question because of its price. Ozone should never be used where other means are just as good. Its use should be restricted to those cases where other means fail to do the work or fail to do it as satisfactorily.

The next best thing after pure drinking water is pure air and this is another achievement of ozone. While it does not sterilize it when dry, yet it takes away nasty odors, like that of tobacco smoke and partly masks, partly oxidizes products of respiration, perspiration, and other volatile matter. Ozone treated air cannot compete with real pure air from the mountains or at sea, but it invigorates when being breathed in adequate dose, by all means not too strong. A proportion of about one in a million is quite enough for ordinary purposes.

It does make some difference to the men in an over-crowded office whether or not the air breathed by every one of them several times over is ozonized or not. Anyone who actually has experienced the great difference in sensation will be able to appreciate fully the beneficial effect of ozone. It has been a mistake, however, to attribute to ozone what it really does not do, viz., sterilize the air.

The beneficial effect is unquestionable. Moreover, the experiment is very easy to try. There are many air ionizers on the market. The energy which these small apparatus require is hardly worth speaking of, as it is of the order of magnitude of that of an incandescent lamp.

USES OF OZONE IN THERAPEUTICS

We must be very short on this subject however important it

may be, as there is very little reliable information to be had on this matter.

There is some evidence that ozone is very beneficial to phthisis patients when in the first stadium. It should certainly be not stronger than in the proportion of one in a million or one in ten million parts of air, when intended for continuous inhalation. This point seems of enough importance to be taken up seriously by some official medical society.

When we consider obesity as the result of inadequate power of oxidation, the body building up no further than to fat instead of going to a higher step of oxidation, for instance, fibre, tissue, flesh, and so on, ozone might be of help.

The therapy of "eating" oxygen in the form of peroxide of barium and other peroxides seems very poor indeed; it is very probable that through inhaling ozone, of course, in very weak concentration, additional oxygen may be brought into the system.

It is dangerous for a layman to discuss matters of a medical nature. It will be better to make one statement which is easily controllable and this is that the inhalation of ozone causes a rise in the percentage of oxyhemoglobin when this happens to be below the normal, and this rise accounts for the supposed beneficial effects.

Cases of chlorose, and all that is connected with the blood in a direct way, may be treated successfully with ozone. But my own personal experience does not go further than the increase mentioned in the percentage of oxyhemoglobin, which suggests or even indicates possible favorable results from proper ozone treatment.

INDUSTRIAL USES OF OZONE

Let us bear in mind what we said about the price of ozone that there never is a chance for ozone where cheapness is the very first question to be considered. But cheapness is not always the main factor. Very often quality comes in as a more important item.

As a bleaching agent ozone has to compete with chlorine. For bleaching paper pulp, however, there are other factors to be considered, like the size of the fibre, which is much better if ozone is used. In fact, when comparing ozone-bleached pulp with chlorine-bleached pulp the difference is striking, the individual fibre being about three or four times as large in the former case. This is worth while considering, for the longer the fibre the more "stuff" can be added to make paper out of it.

The bleaching of wax has been carried out with fair results, but not so striking, as to think much of it. The bleaching of sugar molasses succeeds easily, but at the expense of power of crystallization. This fact does not surprise us, when thinking of the hyper-sensitiveness of sugar to turn to the non-crystallizing kind.

The treatment of milk is a great problem of excessive importance, but the trial of ozone for this purpose leads only to disappointment, since the very tender organic compounds contained in milk, are destroyed long before any of the bacteria are destroyed and this is not surprising.

It may be mentioned here that it was the desire to sterilize milk which in Holland led to the pioneer work of Tindal (Schneller patents). When he saw that ozone would do nothing but harm to milk Tindal was the first to recognize the possibility that ozone might be beneficial to water. I dare say that to Tindal is due the present status of water sterilization by ozone. All that has been done—and that is a great deal—has been the result of his showing the way and full credit should be given to him although usually it is not customary to acknowledge the merit of those who did not succeed themselves but gave the impetus to the success of others. Tindal died some years ago.

The treatment of flax can be carried out with great success with ozone. The process known as rotting consists of having the glue of the stalk destroyed through the development of certain bacteria. This result is desired because when combing the raw flax, particles of glue prevent it from being done so effectively or may cause loss of material.

Ozone-treated flax does not contain any glue or other sticky

matter and thus said treatment improves the product to a great extent, and more especially so the yield of fibre.

It was not until very much later that I found the reason of this favorable result.

I found it by chance when trying the effect of ozone on glue, the purpose being a bleaching of it.

It turned out that ozone bleaches glue effectually but, after having been thus treated, glue did not possess any more of sticking property. For gluing purposes it is no longer suitable, but the same phenomenon explains the beneficial effect of ozone in treating flax.

Another vast field of possibilities is found in the industry of oils and fats. When making varnish out of linseed oil, discoloration is hardly to be avoided on account of the higher temperature used. If, however, the oxidation is performed by ozone it can be done entirely at ordinary temperature. The result is a perfectly transparent varnish of high quality—and of higher price, as may be added.

For the manufacture of surrogates for butter use is being made of cottonseed oil. This oil, however, possesses a rather strong and nasty taste; to take that taste away has been tried and it can be done.

Another problem has been the bleaching of santal oil, a very expensive oil, the bleaching of which is done by aid of sunlight or peroxide of hydrogen.

I have tried ozone for this oil and obtained a very good result.

However, these questions are rather more commercial than technical, for the problem turns out to be this: Does it pay to spend extra money on the purification so as to get a higher price for the product? Such questions cannot be treated in a short condensed summary like this.

There are numberless other possibilities for the use of ozone. Very many have been suggested and perhaps some have been tried. But as I did not want to make any statement in this article unless backed by my own personal experience I cannot give information on those other possibilities, not knowing them from actual tests.

Now that the time has arrived that chemical laboratories can have ozonizers of convenient size, and in case of successful results, can have large ozonizers of any size, it is to be hoped that earnest investigators will set to work in their particular lines and will contribute to the development of the ozone industry.

No antimony was produced in the United States last year from domestic ore, but a considerable quantity was saved in the form of antimonial lead, which is obtained at the smelters of precious metals in the course of their operations, and large quantities of antimonial alloys are recovered from secondary sources, such as scrap bearing and type metals, solder and antimonial lead drosses. From antimonial lead of both domestic and foreign origin, but smelted in the United States, according to figures compiled by the United States Geological Survey, 1949 short tons of antimony were produced, while from old alloys, scrap, dross, etc., 2506 short tons of antimony were recovered.

The Yampa smelter in Bingham canon, Utah, has been offered for sale. It was built in 1904 and for several years treated low-grade copper ores from the vicinity of Bingham. Later the company made an ore contract with the A. S. & R. Co. and the plant was closed, never to be reopened.

Gogo juice is used by the natives in the Philippines in panning gold-bearing sands. The juice is obtained from the bark of a plant and is neither alkaline nor acid. It "sickens" mercury and destroys its amalgamating power; but it is supposed to cause fine gold to settle quickly in a pan and not float away. According to experiments outlined in the Philippine *Journal of Science*, gogo juice has no qualities which would be beneficial in the concentration of gold, but the effect of a spray of the juice on the surface of water in a pan is to cause floating particles of gold to sink. Water sprayed on the pan would have the same effect.

A New Electric Steel Casting Plant

A Stassano Furnace Installation in California

By Ernst M. Schmelz

The first electric furnace of the pure Stassano type in the United States has just been installed by the Warman Steel Castings Company in their foundry at Redondo, Cal., and is

FIG. 1.—ELECTRIC STASSANO STEEL FURNACE

now in daily operation producing small and medium-sized steel castings.

This firm, which was organized three years ago, has hitherto been using Milwaukee-type crucible furnaces with a capacity of 3 tons per day. While the comparatively low price of fuel oil in California would seem to favor this process, this advantage is more than off-set by the higher cost of crucibles and labor.

One of the principle considerations in changing to the electric furnace was the fact that the firm was anxious to extend their trade to produce castings weighing 1600 lb. which is almost impracticable in a small crucible plant. An extended investigation of the various types of electric furnaces, with their particular requirements in view, decided the management on the Stassano type. An important feature influencing their decision was the adaptability of the Stassano 1-ton type for three-phase alternating current, doing away with the expense of a rotary transformer, the use of which is unavoidable if three-phase currents are used with a single-phase furnace.

The distinguishing feature of the Stassano furnace is that the metal is fused by the radiant heat from an electric arc over the metal and in a closed chamber providing a neutral atmosphere for the chemical reactions which take place in the process of refining. This permits of greater accuracy and thoroughness in closely following specified analyses in the production of castings.

The furnace in Redondo, shown in Fig. 1, is built according to the latest Stassano patents. It combines the well-known features of a completely closed melting chamber with a neutral atmosphere, the arrangement of a three-phase electric arc above

the metal, preventing the carbon and all other electric impurities from entering the metal, and allows a thorough mixing of the bath during any desired length of time.

This mixing is accomplished in a way entirely different from the older types of Stassano furnaces. Fig. 2 will explain the construction. A pair of bevel gears placed underneath the furnace and driven by a small electric motor causes the rotation of a shaft which is affixed to the center of the furnace bottom and thereby keeps the axis of the furnace always inclined at an angle to the perpendicular. The furnace is suspended by two trunnions in a horizontal steel ring, and this ring, in turn, swings by means of another pair of trunnions from supports in the same plane, but 90 deg. around from the first pair of trunnions.

This double suspension, which is the same as is used in a ship's compass, transforms the rotating movement of the furnace bottom into an oscillating movement of all furnace parts above the plane of the trunnions. In this way the water connections for the cooling of the electrodes and for the electrode hydraulic control, as well as the cable connections between switchboard and furnace, are extremely simple, while the old type of rotating furnace was rather complicated in this respect.

The furnace has a capacity of 2000 lb. to a charge and can be tilted to pour either the entire charge at once into a bull ladle or as required into small handle ladles for the pouring of small and thin-walled castings.

The electric current is supplied by the Southern California Edison Company, in the form of three-phase alternating currents at 10,000 volts and 60 cycles, and will eventually be brought down to 100 volts and 150 volts respectively by three single-phase transformers, arranged in the so-called interconnected star. Temporarily, however, until these transformers are ready, two sets of three single-phase transformers are installed, each having a ratio of 10,000 volts to 2200 volts and 2200 volts to 110 volts respectively.

As raw materials are used the mis-run castings, risers and gates, which accumulated in great quantities from the crucible process, and a small percentage of shearings, etc., supplied by local machine shops

FIG. 2.—VERTICAL SECTION OF STASSANO FURNACE

The first heat from the furnace was taken on Oct. 27, and showed remarkably good results. The wattmeter installed by the power company was unfit for the control of the operations, its smallest unit being 200 kwh, but there is a recording wattmeter in the line which keeps an exact record of the operation.

FIG. 3.—POWER CURVE DURING THE TWO FIRST CONTINUOUS

The diagrams of two consecutive heats taken off on Oct. 27 are reproduced in Fig. 3. They show, in the first place, how steady the demand of the furnace is. In spite of the fact that during the whole time the regulation of the furnace was operated by unskilled men, who until the day before had never seen an electric furnace, the demand varied hardly more than 10 per cent above or below the average.

The current consumption per ton, taking into consideration the transformer loss, figures 964 kw-hours and 1009 kw-hours per ton of charge respectively, and the time for each heat starting from a cold charge was 5 hours and 30 minutes and 5 hours and 1 minute respectively. Considering the lack of skill on the part of the men, and the fact that the current-saving arrangement of the new transformers was not yet installed, this record must be called a very good one. The writer hopes in the near future to report a further reduction, both in time and current consumption at this plant.

The metal, which proved to be extremely hot, poured to the last ladle in small castings for automobile parts. Neither a chemical analysis nor a test of physical properties has been made at the time of this writing, but the fractures at the gates showed a good grain and the castings appeared to be sound. Unfortunately the writer was unable to make further tests, being called away for the completion of another plant of the same kind in an Eastern foundry, which is expected to start operation before the end of the year.

Los Angeles, Cal.

Cost of Transportation to South America

Foreigners contemplating the purchase of American goods want to know the cost of the article delivered, and the inability or unwillingness of American exporters to quote c. i. f. prices has lost them many orders. To assist exporters in ascertaining delivery charges, the Bureau of Foreign and Domestic Commerce has published a bulletin compiled by Commercial Agent F. J. Sheridan dealing with transportation rates to the west coast of South America, this section of the foreign field being selected because of the trade activity that is expected to follow the opening of the Panama Canal. The main part of the bulletin is a series of tables giving the freight rates on over 800 articles from inland points in the United States to inland points in Ecuador, Peru and Chile. Freight rates per 100 pounds, in carload and less than carload lots, are given to New York from Chicago, St. Louis, Cincinnati, Indianapolis, Cleveland, Detroit, Buffalo, Pittsburgh, Boston, Providence and Hartford; ocean freight rates per 100 pounds and per cubic foot from New York to Guayaquil, Callao, Mollendo, Antofagasta and Valparaiso, via the Straits of Magellan and via Panama, and freight rates per 100 pounds inland from Guayaquil to Quito, Callao to Lima, Mollendo to Arequipa and Valparaiso to Santiago. Lighterage, transfer and other charges at the port of New York and at South American ports are shown, together with the cost of marine insurance, and data are also given as to consular fees and regulations and steamship requirements. Comparative tables give the competitive rates from European ports and from New York to South America. In addition to these features, statistics are furnished to show the character of the goods sold by the United States to Ecuador, Chile, Peru and Bolivia and for each of

these countries general information is given as to area, population, language, currency, postage rates, foreign trade and distance from New York. Tables of price comparisons give the equivalents in the currency and measures of these countries of prices stated in the money and measures of the United States. The bulletin, in short, is a compendium of practical information for the assistance of merchants who are engaged in the export trade or who contemplate entering the foreign field. Copies of the bulletin (Special Agents' Series No. 72) may be obtained from the Superintendent of Documents, Washington, for 10 cents each.

A New Type of Electrical Furnace for the Reduction of Ores

By Francis Louvrier

In view of the many well known advantages of electricity as a source of heat, the slow development of electrometallurgy is rather surprising. Of course, numerous obstacles had to be surmounted in this development.

Most electric furnaces in use at the present time can use only

PLATE I.—SECTIONS OF FURNACE DESIGNS FOR IRON, COPPER, AND LEAD ORES

a small power, and their output is limited mainly on account of the shape of the furnace and the arrangement of the electrodes.

Temperature regulation is difficult, if carried out, by means of movable electrodes, as these are heavy and usually immersed in the charge. While it may not be easy, yet it is always possible to remove the electrodes further away from each other, so as to lower the temperature in the furnace. But the reverse operation—bringing the electrodes nearer together in order to increase the temperature—may be impossible because the charge is in the way.

In certain furnaces the electrodes are put on a slant and have to bear the weight of the charge. There is the danger

RUNS OF THE ELECTRIC STEEL FURNACE

of breaking at any moment. Further, the thermic efficiency of many electric furnaces actually in use is unsatisfactory: their consumption in electrode material is too high, and so on. Difficulties of this kind have held back the development of electrometallurgy. To overcome them has been the purpose of the furnace design which is the subject of this article.

This type of furnace, which is the invention of F. Louvrier and C. Louis, is characterized by the use of electrodes which are practically fixed, and the regulation of temperature is accomplished by simple manipulation of switches, by means of which the number of electrodes in circuit or the position which they occupy toward each other can be varied.

The general arrangement of the furnace is indicated by Plate 1, which represents a polyphase furnace.

Fig. 1 is a vertical section along 3-3 of Fig. 3. Fig. 2 is another vertical section along 4-4 of Fig. 4. Fig. 3 is a horizontal section along 1-1 of Fig. 1. Fig. 4 is a horizontal section along 2-2 of Fig. 2.

The furnace proper consists of three principal parts—the shaft *A*, wherein the progressive heating of the ore takes place, the bosh *B*, which is the zone of reduction, and the crucible *C*, where the molten metal accumulates. The crucible and the reduction chambers are lined with very refractory and non-conducting material *D*. The bottom *S* of the furnace is conducting and is connected with one of the phases of the current. It is made from varying material to suit each particular case; for instance, for iron ore reduction it is made of a piece of cast iron, with some cooling arrangement.

A series of openings are horizontally disposed at various heights in the two opposite walls of the bosh. Through each of these openings passes a well-fitting electrode. These electrodes form two symmetric series, opposite to each other. Each of the series corresponds to a phase of the current and each electrode in the series can be connected with its corresponding phase by means of a switch.

In smaller furnaces each electrode takes up the whole width of the furnace; in larger furnaces two or three electrodes are arranged at the same horizontal height side by side, as shown in Fig. 4, so that the size of each electrode remains within reasonable limits.

The electrodes of each series are insulated electrically from the other series by the furnace wall, which is non-conducting. The electrodes are pushed through the openings into the furnace so that they touch the charge without being immersed in it. The small space between the furnace wall and the electrode is luted in order to avoid leakage of the gas formed inside the furnace.

The top of the furnace is provided with the charging arrangement, a safety valve and the necessary pipes for the removal or recovery of the furnace gases.

When the carbon monoxide which develops from the reduction of the ore is to be burned in the furnace itself, the hot air necessary for the combustion is blown in through the tuyeres *J*.

The electric current passes through the charge between the two series of lateral electrodes and between these and the bottom electrode. The charge acts as resistor, and as all parts of the charge are traversed by the electric current, a practically uniform temperature is obtained.

Evidently the current passing through the charge and consequently the temperature in the furnace depend on the number of lateral electrodes that are connected to the circuit and on the relative position which they occupy.

The temperature is always easily regulated by a simple movement of the electrode switches. The electrodes themselves are, therefore, immovable or nearly so, all that is necessary is to push them in from time to time in order to compensate for their consumption. As air cannot enter the furnace and as no hot gases circulate around the electrodes, this consumption is relatively small and the compensation need only take place once or twice in a week.

The crucible *C* is provided with two tap holes, one for the slag and the other, *M*, for the metal.

For operation with single phase or continuous current the furnace is arranged in the same way. One possible arrangement is a conducting sole connected to one pole, and a series of lateral electrodes occupying two opposing walls of the furnace and all being connected to the other pole of the circuit. Another possible arrangement uses two lateral opposite series of electrodes connected to the two opposite poles of the circuit, without a conducting sole.

In plate 1, Fig. 3, a refining crucible *T* with accessories (tuyeres *O*, chimney *G*, etc.) is shown, this is intended for the refining of copper.

This furnace has the following advantages: Simplicity of construction; ease of regulation of temperature by a single movement of the electrode switch; the possibility of using a high voltage, such as 120 volts in small furnaces, 240 volts in medium-sized furnaces, and 350 to 400 volts in large furnaces, according to the ore under treatment. These are the usual supply voltages, so that the electric furnace may be connected directly to the lighting and power circuit. These furnaces can be built in large sizes, even above 40,000 hp, according to the inventors. For instance, a large three-phase furnace may have a reduction chamber *B* 5 meters (16 ft.) wide on top and 3 meters (10 ft.) at the bottom. There are above each other five horizontal series each of three electrodes with dimensions 0.25 meter and 1.10 meter (0.8 and 3.6 ft.). The section of the electrodes per phase is therefore $25 \times 110 \times 3 \times 3 = 41,250$ sq. cm., which allows of the passage of a current of at least 50,000 amp (if we allow 120 amp per square centimeter).

If in such a three-phase furnace the voltage between the phases is 400 volts, the power is $50,000 \times 400 \times 1.732 \times 0.925$ watts or 43,000 hp, the power factor of the furnace being assumed to be 0.925.

A similar furnace operated with single-phase current would have a capacity of 50,000 hp and with continuous current it would exceed 54,000 hp.

A furnace of 40,000 hp could produce, according to the inventors, 500 to 550 tons of pig per day; it could handle 220 to 280 tons of copper ore, or 600 tons of 50 per cent. concentrate.

Another advantage of the design is that the furnace is completely enclosed so that no gases can escape nor is the outside air able to enter.

The consumption of electrode material is considerably reduced since the hot gases do not circulate around the elec-

trodes and these latter can only be used up at their ends. With the exception of the ends the electrodes are out of reach of the high heat and of combustible gases, air and oxygen.

Considerable reduction in manual labor results from the large capacity of the furnace and from the facility of regulation: on account of the small consumption of the electrodes these have only to be readjusted in their positions once or twice a week.

Heat losses are avoided, except the loss by radiation, and this is small on account of the large size of the furnace.

The heat carried upward by the gases is utilized in the upper portion of the furnace for preheating the charge.

The gases, as far as they are combustible, can be burned in the furnace itself and their inherent heat may thus be utilized. Or it is possible and easy to recover completely the gases in case this is desired.

On account of the advantages just mentioned the efficiency of the furnace is high.

A uniform temperature is obtained in the whole part *B* of the furnace so that the reduction zone comprises the whole of part *B* and is not limited to a small space between two or more electrodes of small cross-section.

A uniformly progressive rise in temperature is obtained from the top of the furnace toward the lower part of the reduction zone.

The operation of the furnace is absolutely continuous, without interruption for the replacement of electrodes.

REDUCTION OF IRON ORES AND PRODUCTION OF PIG IRON OR OF CRUDE STEEL

For the reduction of iron ores the furnace is used as shown in plate 1, with or without supplementary crucible. This crucible can be installed where the direct production of cast iron or crude steel is intended.

The upper part of the furnace may be provided with tuyeres *J* for supplying the hot air necessary for the combustion of the carbon monoxide which rises upward from the reduction zone in the furnace.

The consumption of electrical energy in a Louvriér-Louis furnace which treats 50 per cent ore should not exceed 14-hp year per ton of pig iron produced, and would be reduced to 15-hp year when the carbon monoxide is burned inside the furnace.

The expense for electrodes should not exceed 8 cents per ton of pig produced.

The advantages may thus be summed up:

1. Possibility of transforming smelting furnaces in actual use into electric furnaces
2. Output as large as in blast furnaces: a large electric furnace can easily produce 600 tons of pig iron per day.
3. Better quality of product, since the electrical energy does not introduce any impurity (sulphur, phosphorus, etc.), which is always contained in the coke.
4. Possibility of directly producing crude steel, by having the molten metal during its reduction in contact with a smaller amount of carbon, and by employing pure ores.
5. Reduction of treatment cost, electrical energy, electrodes, reducing carbon, flux, manual labor, general expense, upkeep, amortization, etc., which, as estimated by the inventors, can be reduced to \$5.20 per ton of pig in countries where cheap water power is abundant and where reducing carbon can be obtained at \$7.50 per ton.
6. Possibility of using the heat of the carbon monoxide which rises during the reduction of the ore.

Before adopting the furnace just described, Messrs. Louvriér and Louis had patented and recommended another type of furnace which was characterized by its movable vertical electrodes between the charging stacks. This type of furnace was offered by its inventors in 1908 to the Noble Electric Steel Company for its Heroult plant at Pitt, Shasta County, California.

This now ancient Louvriér-Louis type is in actual use at the Heroult plant at Pitt, with some slight modifications in

the shunting of the current, which were introduced by Mr. R. E. Frickey (see *Metallurgical and Chemical Engineering*, July, 1913).

This type of furnace with charging stacks has been abandoned by its inventors since 1910 and has been replaced by the furnace above described, which gives much superior results.

REDUCTION OF COPPER ORES

The general arrangement of the furnace is exactly as shown in plate 1. The lower part of the stack *A* is fitted with tuyeres *J* which supply hot air which is required for the oxidation of the ore and the combustion of the sulphur.

A crucible *T* serves for the refining of the matte. This crucible, which is built close to the furnace, communicates with it by an ordinary tap hole *M*, which can be opened or closed from the outside. This crucible is provided with a door *P* made from refractory material. This door also serves for introducing into the crucible the materials (silica, etc.) which are required for refining the matte.

Tuyeres *O* are arranged in the lower part of the crucible for blowing in hot air into the center of the matte.

The hot gases resulting from the refining can be led off into the upper part of the furnace by the chimney *G* into the annular space *H* and through the openings *K* in order to utilize their heat.

The crucible works intermittently while the furnace operation is continuous. It is also possible to use two crucibles as described and placed symmetrically one on each side of the furnace.

The consumption of electrical energy per ton of ore (with 5 to 6 per cent of copper) should be between 0.06 to 0.03-hp year, according to the nature of the ore and its sulphur contents. The cost of electrodes should amount to about 2 cents per ton of ore treated. The inventors claim the possibility of treating in one furnace 2000 to 2500 tons of medium-grade ore per day with a considerable reduction of operating costs. Including general expense and amortization these are estimated by the inventors to amount to \$1.20 per ton of ore treated in the case in which the smelter produces its own electrical energy from water power.

TREATMENT OF LEAD ORES

The arrangement of the furnace is almost the same as described for copper ores. We will, therefore, refrain from further description.

REDUCTION OF ZINC ORES

Plate II shows the arrangement of the furnace in this case. The interior of this furnace is divided into two compartments by a horizontal refractory partition with a central opening for the passage of the ore. The lower chamber forms the actual furnace, in which the reduction of the ore takes place, while the upper chamber serves for the drying and the preheating of the charge. The partition also serves to economize space and facilitates the withdrawal through the lateral openings *O* of zinc vapors and of the carbon monoxide produced in the furnace.

These openings *O* lead into side chambers *R* and *R'*, built onto the walls of the furnace (Figs. 2 and 3 of plate II). In these chambers the vapors of zinc are separated from the carbon monoxide before they pass into the condensers. The separation takes place by gravity only: the heavy zinc vapors sink to the bottom while the carbon monoxide goes to the top and passes into the upper portion of the interior of the furnace.

The use of these side chambers is further intended for the lowering of the temperature of the zinc vapors to a degree intermediate between the temperature of their production inside of the furnace and between the liquefaction in the condenser.

In order to effectively separate the carbon monoxide gas and the zinc vapor it is necessary that the quantity of gases and vapors entering is equal to the quantities escaping at any time.

For this purpose a valve *V* regulates the escape of the zinc vapors to the condensers through the tubes *H* and *K* (Fig. 2) and the adjustment of the valve is based on the indications obtained through the two taps *N* and *Z*, which are placed at

convenient heights in the lateral chambers. When the furnace works normally, the upper tap *X* must give carbon monoxide on opening; the other tap *Z* must show zinc vapors.

When the furnace works normally the proper adjustment of the valve *V* is easily found by experiment, for the production of gas and zinc vapors inside the furnace remains fairly constant.

The temperature of the condensers is uniformly maintained between 600 and 700 deg. C. The consumption of electrical energy per ton of 50 per cent zinc ore amounts to 0.2-hp year.

The expense for electrodes amounts to about 8 cents per ton of ore.

These advantages are claimed by the inventors:

Zinc is obtained as molten metal and not as "blue powder"—the proportion of blue powder does not exceed 3 per cent of the metal.

PLATE II.—SECTIONS OF ELECTRIC ZINC FURNACE

The better condensation of the zinc vapors is facilitated by their separation from the gases of reduction and by the previous lowering in temperature in the side chambers.

Most of the faults are suppressed which cause losses in metal so that a yield of at least 96 per cent of the zinc contents of the ore is obtained.

The chemical reactions are not disturbed by foreign factors, like air, moisture, etc., which may be contained in the charge, as these are completely removed before the ore arrives in the reduction zone.

The operation is continuous and adapted to large-scale working—600 tons can be treated per day by a single furnace.

Further advantages claimed are improved thermal efficiency, reduction in cost of handling, diminution in the amount of

reducing carbon and the possibility of roasting the ore without expense for fuel, by utilizing in the upper part of the furnace the heat developed from the combustion of carbon monoxide which rises upward from the reduction zone.

These advantages result in a reduced operating cost. The total cost of treatment, including general expense and amortization is estimated by the inventors at \$5.25 per ton of ore treated in case the electricity is generated by means of water power.

In a paper presented at the recent meeting of the American Electrochemical Society in Denver Messrs. Dorsey A. Lyon and Robert M. Keeney arrived at the following conclusions: "The chemical conditions leading to the formation of blue powder are due largely to the speed of reduction of zinc oxide in the electric furnace and to the presence of volatile impurities in the charge. . . .

"In the electric furnace, the temperature directly beneath the electrode in either the arc or the resistance furnace is so high that the reduction proceeds so rapidly that the large amount of carbon dioxide formed does not have a chance to be reduced to monoxide by the hot coal of the charge before entering the condenser.

"Hence there is oxidation of the zinc.

"By the use of electrodes of large cross-section it is probable that this concentrated heating could be reduced so that, rather than a very high temperature at one place there would be a uniform comparatively low temperature all over the charge. . . . Or the current could possibly be distributed more evenly by flat electrodes of rectangular cross section."

It can easily be seen that the Louvrier-Louis furnace fulfills all the conditions mentioned by Messrs. Lyon and Keeney.

In a paper presented at the same meeting Mr. Woolsey McA. Johnson stated that the electric reduction of zinc ore would be solved if the following conditions could be properly fulfilled:

"1. A first-rate preheater, mechanically strong and machine operated. Preheating *per se* has no advantage save to reduce kw-hours per ton of ore. Preheating must be done right, not too hot and not too cold, with a progressive application of metallurgical means.

"2. The flow of heat through the charge in the electric smelting furnace and slag must be under perfect control. The electricity must be controlled and care must be taken that the zinc globules in eductor assume no static charge otherwise coalescence of the spherulites is hindered.

"3. A regular flow of pure zinc gas must be delivered at proper temperature to the condenser.

"4. The condenser must be durable and under good metallurgical control."

Finally, Mr. Peter A. Peterson at the same meeting summed up his conclusions on this important problem in the following manner:

"It is necessary to have the charge absolutely dry. The presence of water even in small quantities is serious, due to the oxidizing of the zinc vapor by decomposition of the water. What is still more serious is the instantaneous generation of steam and other gases, causing a great increase in the velocity of gases, thus disturbing the condensation of the zinc in the condensers and thereby causing a loss of zinc and also a loss of silver and other metals, due to furnace charge being blown outward into the condenser.

"If it is not possible to mix the charge with hot calcines from the roasting furnace and then immediately feed it to the electric furnace, there must be a preheating furnace to heat the charge before introducing it into the electric zinc furnace."

All, or nearly all, of the conditions mentioned by Messrs. Lyon and Keeney, Johnson and Peterson are practically fulfilled in the Louvrier-Louis furnace.

Most of these conditions have already been mentioned by the writer in the article entitled "Causes of the Practical Non-success of Electric Furnaces in Treating Zinc Ores," which appeared in *Metallurgical and Chemical Engineering* of November, 1912.

Notes on Chemistry and Metallurgy in Great Britain

(By our Special Correspondent)

The New Headquarters of the Institution of Civil Engineers

The new building of the Institution of Civil Engineers has been almost completed. It is a very elegant structure, with a frontage of about 170 feet to Great George street, and 140 feet to Princes street when the whole design shall have been carried out.

The building is constructed of steel framework with an exterior of Portland stone, with the main entrance, which is ornamented with some very fine sculpture, in Great George street. The north and south reading-rooms are on the ground floor, and the latter apartment gives access to the council chamber and committee room; and a small hall also occupies part of the western side, while the eastern side is devoted principally to offices.

The main library is on the front of the first floor, has a length of 147 feet and a width of 28 feet 6 inches, and the old oak fittings and panelling from the building recently demolished have been used as far as possible, whilst the new panelling required, in consequence of the larger size of the new library, has been made to correspond in style. On the second floor is a similar upper library.

The chief apartment of the building is the great hall, which has a length of 100 feet and is also 45 feet in height on the Princes street side. Its mural decorations are in marble, and the ceiling is finely decorated. Three large hinged panels divide the hall from the lecture theater, which is almost exactly on the lines of the theater of the old building, and is of the same dimensions. The old oak dado was removed and has been utilized in the new theater which very closely resembles, even to the dome lighting, the theater of the old building so familiar to engineers from all parts of the world.

Electric lighting is used throughout the building. The heating is mainly by steam radiators, and adequate ventilation has been provided everywhere.

Oil-Shale in Skye

From details recently published by the Geological Survey it appears that the shale discovered in the Island of Skye is of considerable extent and reaches from fully five miles north of Portree to about the same distance south of that place. How far the seam extends westwardly cannot be ascertained at present, but for a good way inland it is at a workable depth and the dip is slight. No outcrops have been located inland, and the deposit is below strata of other rocks. The outcrop south of Portree shows evidence of the action of heat in most places; but to the north more than a mile and a half of the seam has been found free from this defect.

The thickness of the shale-seam at the outcrops varies from 7 feet to 10 feet. Analysis of the shale from the coast of Skye gave 12.8 gallons of crude oil and 7.4 lb. of ammonium sulphate per ton; whilst a sample from the Island of Ramsay—where the first discovery of the shale was made—gave 12 gallons of crude oil and 6.2 lb. of ammonium sulphate per ton.

The chemist who made the analyses found the specimens to be so excessively weathered that he did not expect more than a very small yield, and the true value of the shale cannot be stated until borings are made to procure unweathered samples for analysis. It is certain that new samples from the bores would show a great improvement on the figures given by the outcrop specimens; but the profitable working of the seam depends on its being rich enough to compensate for the increased cost of coal, chemicals and transport which the situation of the deposit must entail.

The Supply of Nitric Acid in England

It is now several years since some of our leading chemists warned us that England should be made independent of foreign sources for the production of nitric acid and nitrates, both for fertilizing purposes and for the manufacture of ex-

plosives in war time; and at length there is a prospect that this country will soon be in a position to manufacture all the nitric acid which will be required.

Steps are being taken for the erection of works at Dagenham, on the Essex shore of the Thames, which will be capable of producing 12,000 tons of nitric acid a year from cyanamide, and to establish a plant with a similar capacity at Trafford Park, Manchester; in addition to which it is proposed to put down plant in Scotland to turn out 9000 tons of nitric acid a year, and in Ireland for an output of 3000 or 4000 tons. The production of cyanamide will be such as will permit heavy reserves being kept in store, but in case of necessity any waste products such as ammoniacal liquors could be utilized. It is understood that the whole of these works will be controlled by the Nitrogen Products & Carbide, Ltd.

The British Aluminium Company

The British Aluminium Company has entered into an agreement with the Burgh authorities of Burntisland to acquire some 40 acres of ground for the establishment of new works close to the town on a site outside the Borough boundary and near the road to Aberdeen, and also for the possession of further ground for waste products and ulterior developments. The new factory will be in proximity to the main line of the North British Railway Company and easily accessible from Burntisland Harbor. It is estimated that the new works and plant, which are to be completed within a year and a half, will involve an outlay of about £200,000, and that from 300 to 400 hands will be employed.

Engineering Imports and Exports

The returns issued by the Board of Trade show that for the nine months ended on the 30th September there were fair increases in the values of imports and exports of engineering materials and products as compared with the corresponding period of last year, but the statistics for the month of September are not so satisfactory, and exhibit a general decline in exports except for machinery and new ships. For the nine months the imports of iron and steel, including manufactures, amounted to £11,192,013, an increase of £1,950,693; and exports totalled £40,962,292, an increase of £6,413,021. Other metals, including manufactures, were imported to the value of £24,193,890, an increase of £1,962,947; and were exported to the value of £9,927,750, an increase of £1,288,405. Imports of machinery are put at £5,444,611, a rise of £448,782; and exports went up to £27,489,564, an improvement of £3,433,170. New ships reached £27,031 for imports, and £9,139,800 for exports, showing increases of £1,723 and £4,706,767 respectively.

Taking the figures for the month of September alone, imports of iron and steel increased £21,445, but exports decreased £531,817; imports of other metals rose £284,733, whilst exports fell £162,765; in electrical goods and machinery the imports were £27,429 higher, and exports were £109,052 lower; machinery showed an increase of £33,265 in imports, and an increase of £172,895 in exports; the value of new ships imported was greater by £2,407, and exports improved to the extent of £100,005.

The New Engineering Laboratories at Dundee

In the middle of October the new engineering laboratories at University College, Dundee, were opened by Sir A. B. W. Kennedy. In the north block, which is two stories high, are situated the hydraulic laboratory, drawing offices, lecture rooms, the library and rooms for the contemplated architectural department. The tank which furnishes the water supply for the hydraulic laboratory has a capacity of 10,000 gallons, and is placed in the central tower 80 feet in height, which contains the appliances for the ventilation of the building. The water pressure available corresponds to heads of 65 feet, 140 feet and 600 feet. The equipment of the hydraulic laboratory includes a flume 45 feet long by 3 feet wide, an inward flow pressure turbine, a high-speed Oddie-Barclay reciprocating pump, an electrically driven centrifugal pump throwing 450 gallons per minute and a Pelton wheel.

The eastern wing provides for the boiler-house, the heat engine laboratory, workshop, physical testing laboratory and a separate room for cement testing. The engine room contains a horizontal tandem compound steam engine of 100 h.p. at 100 r.p.m. with a boiler pressure of 250 lb. per square inch. Steam is supplied from a Babcock & Wilcox boiler and superheater with a Green economizer evaporating about 1500 lb. of water per hour under ordinary conditions; and an electrically driven Worthington surface-condensing plant operate in connection with the engine. There are also fans for forced draft and a carbon-dioxide recorder.

The National Gas Engine Company contributed a 30 h.p. gas engine and a suction gas producer; and there is a 14-16 h.p. Argyle Petrol engine. Space is reserved for a Diesel engine and a steam turbine which will probably be provided in the near future. The equipment of the physical testing and cement rooms includes a 50-ton single-lever Buckton testing machine, an alternating stress machine, elasticity and rigidity apparatus, and a cement testing machine. The total cost of the building and equipment amounts to £17,000, toward which the Carnegie Trust for the Development of the Scottish Universities contributed £10,000.

A Rapid Method of Estimating Phosphorus in Steel

Accurate results are claimed for the process devised by Haripada Bhattacharyya (*Journ. Soc. Chem. Ind.*, 1913, 32, pp. 738-739). The steel is dissolved and the yellow precipitate of ammonium-phospho-molybdate is obtained and filtered off in the usual way, and the precipitate is washed with 1 per cent. nitric acid until quite free from iron: a 1 per cent. solution of potassium nitrate is then employed to completely wash out the nitric acid, when the filter paper with the precipitate on it is placed in a wide-mouthed 200 c.c. flask and 20 c.c. of N/10 soda solution are added. The excess of soda is estimated with N/10 hydrochloric acid, using phenol-phthalein as an indicator. The sodium hydroxide reacts with the phospho-molybdate according to the equation $(\text{NH}_4)_3\text{PO}_4 \cdot 12\text{MoO}_3 + 24\text{NaHO} = (\text{NH}_4)_3\text{PO}_4 + 12\text{Na}_2\text{MoO}_4 + 12\text{H}_2\text{O}$.

Market Prices

October, 1913.

Tin opened at £186, 10s. and fell away to £184, 15s. on the 17th rose to £185, 12s. by the 9th, dropped a little and again rose, reaching £186, 15s. on the 16th, and has since remained lower at £184, 10s. or about. Closes at £182.

Copper.—Opening at £74 the price gradually fell until the 15th, when it was at £71, 15s., it then recovered by degrees, rising to £75, 2s., 6d. on the 21st, and after a loss of 15s. again reached £75 on the 27th. It closes at £72, 15s., od.

Haematite opened at 66/6 and kept this price throughout the month, closing, however, 63/3.

Scotch Pig opened at 60/6 and fell away to 59/1½ on the 9th; recovered to 58/9 on the 10th and fell again to 57/7½ on the 13th; after reaching 58/- on the 22d it again fell to 57/6 and closes 56/9.

Cleveland opened 54/6, but had reached 53/7½ on the 7th and 51/7½ on the 13th, it then rose a little, but weakly, and was down to 51/10½ on the 17th, and 51/7½ on the 27th, and closes 50/9.

Lead opened at £20, 15s., 0. and fell slightly to £20, 5s. by the 8th; recovered next day to £20, 10s. and to £20, 15s. on the 15th, remaining at the latter price, but closing £21.

Recent Chemical and Metallurgical Patents

Gold and Silver

Solvent for Precious Metals.—Halogen cyanides have been found good solvents for gold and silver, and the bromo-cyanide process is extensively used in Australia. Care must be exercised in the preparation of bromocyanide, or bromine will be wasted. A new method of generating halogen cyanide in connection with an oxidizing agent has been patented by Dr. HANS FOERSTERLING, of the Roesler and Hasslacher Company, of Perth Amboy, N. J. The inventor melts sodium bromide and sodium cyanide in the proportion of one molecule of each, and allows the mixture to solidify. No decomposition takes place in this process. In order to convert this into bromocyanide, it is treated with an acid solution of hydrogen peroxide, and the reaction proceeds as follows:

If an acid was not used, sodium hydrate would form, and destroy the bromocyanide. The rapidity of formation of bromocyanide according to the above equation depends on the concentration of the solution. The formation of the corresponding chlorine and iodine cyanides according to the same formula, is much more rapid than the formation of bromocyanide.

In the practical use of this invention in ore treatment, the mill operator would receive the correctly proportioned mixture of sodium bromide and sodium cyanide, and all that would be necessary would be to dissolve the salt and add an oxidizing agent. An acid solution of hydrogen peroxide is preferred for this purpose, because it is stable when formed by dissolving sodium peroxide in an excess of acid. Three parts of sodium cyanide should be used with one part bromocyanide in order to dissolve gold, thus:

Sufficient cyanide can be added originally to the alkali bromide to give a mixture that will act in a manner equivalent to the two equations:

The largest part of the alkali halogen is not lost in practice, and only so much need be added as to make up the small loss.

Combined Pulp Agitator and Thickener.—In the cyanide process, the steps of thickening and agitating the ore pulp in solution are carried on separately. In Fig. 1 is shown an apparatus in which it is proposed to perform the two operations within the same tank, thereby reducing the cost of apparatus and its maintenance. The device is the patented invention of Mr. J. V. N. DORR, and embodies the principles of his continuous thickener and an air-lift. A partition in the form of a truncated cone divides the tank into two compartments in which the different processes of decantation and agitation can be carried on without interfering with each other.

A flat-bottom tank A, with overflow launder H, contains a

partition E in the form of a truncated cone, dividing the tank into the compartments Y and X. Within the inner compartment is an air-lift C supplied with compressed air from pipe D. A central shaft K is operated by the mechanism ML, and carries at its lower end four radial arms J fitted with rabblers which tend to rake settled solids toward the center.

The proposed operation is as follows: The pulp is fed through launder B to an annular distributor G. The solids tend to settle, while the clear solution flows from the tank at the peripheral launder H. The settling solids are raked to the center by the arms J, where they are acted upon by the air lift, raised and discharged within the compartment X. Thus the solids, which require aeration and agitation to cause dissolution of their precious-metal content, are given the additional treatment required. A portion of the thickened and agitated pulp is

FIG. 1.—COMBINED THICKENER AND AGITATOR

constantly drawn off through the pipe I. Several modifications of the apparatus can be designed, introducing several concentric cone partitions, with a plurality of air-lifts. (1,076,666, Oct. 28, 1913.)

Copper

Apparatus for "Amphidizing" Ores.—In this journal, April, 1913, page 218, reference was made to the Bradley process for "amphidizing" copper ores, being a method of rendering copper soluble, as sulphate. In a recent patent granted to Mr. CHARLES S. BRADLEY, of New York City, the inventor gives a description of the "amphidizer" or oxidizing roaster used to convert the copper ores into soluble condition. The device is essentially a rotary kiln with interior passages so arranged that the ore passes from one end to the other and back again before it is discharged with its copper in soluble form. Heat is supplied through a central passage, and the ore coming in is heated continuously and in a regenerative manner due to the fact that the returning ore transfers some of its heat to the incoming charge. (1,077,036, Oct. 28, 1913.)

A chemical filter, specially adapted to the filtration of acid, corrosive pulps, is the basis of another patent granted to Mr. BRADLEY. As shown in transverse vertical section in Fig. 2, it is a flat filter bed with a foundation to and side walls 11 and 12 composed of concrete. The filtering medium is porous silica brick molded with suitable channels and passage ways connecting with the conduits 19, the latter being connected with sources of vacuum and pressure as desired. The pulp to be filtered is delivered into the channels 15 and 16 in the side walls, and flows onto the bed by way of the ports 18. Vacuum being applied, the solution is drawn through the brick filter into the passage ways and finally to the channels 19. The filtered pulp remains on the surface, and is removed by a traveling scraper which is set to remove all but a thin layer of the material. After this is accomplished, air may be forced through the filter bed from beneath, and the thin layer of

solids blown from the pores of the filter. This becomes mixed with the next charge, and the bed is in condition for another filtering operation. (1,077,037, Oct. 28, 1913.)

Metallurgical Furnaces

Improvement in Ore Roasting Furnaces.—In that type of ore roasting furnaces used for desulphurizing blende or pyrite, having an annular rotating hearth and stationary annular arch to which rabblers are attached, it has been discovered by

FIG. 2.—FILTER FOR ACID PULPS

NAVIER DE SPIRLET, of Brussels, Belgium, that incipient fusion of the sulphides may occur on the hearth at the point of feeding. M. de Spirlet proposes to obviate this difficulty by arranging ventilating passages in the roof or arch of the furnace and the suspended rabblers, through which air or gas can be passed for the purpose of removing some of the heat concentrated at the point of incipient fusion. (1,077,010, Oct. 28, 1913.)

Air-Cooled Rabble Arm.—The rabble arms used in roasting furnaces of the superimposed-hearth type are usually cooled by allowing air to pass through them by way of the hollow central shaft. An improvement in the manner of cooling has been patented by MAURICE VAN MARCKE DE LUMMEN, of Cologne, Germany, as shown in Fig. 3. The arms are made in one piece in the form of a hollow body containing a longitudinal partition *k*, which divides the interior of the arm into two compartments. The passage or compartment *l* registers with a central opening in the hollow shaft at *o*. Each passage *m* terminates at the central part of the arm in an opening that communicates with lateral passages *q* in the hollow shaft. By this arrangement the cooling air rises through the central part of the shaft, traverses the upper and lower passages of the arms, and makes its exit through the lateral passages in the shaft. (1,076,297, Oct. 21, 1913.)

Heat Regenerator.—In the use of the cheaper grades of gas fuel in metallurgical furnaces, difficulty is sometimes experienced in maintaining a sufficiently high temperature in the furnace to produce a neutral or reducing action. The object of an invention of Mr. THEODOR L. HOLLE, of St. Louis, Mo., is to overcome this defect by preheating the air introduced into the furnace to a high temperature. This is accomplished by a plurality of circuitous passages or flues alternately arranged

FIG. 3.—AIR-COOLED RABBLE ARM FOR ROASTING FURNACES

for the passage of air and gases of combustion in opposite directions, so that the outgoing products of combustion passing from the furnace to the stack will highly heat the flue walls, and the incoming air traveling in the opposite direction in adjacent flues will receive heat in proportion to the temperature of the walls. A relatively large number of flues are arranged in a small space, and special structural units are used. (1,076,426, Oct. 21, 1913.)

Water-Cooled Port for Open-Hearth Furnace.—In Fig. 4 is shown a longitudinal section through one end of an open-hearth furnace, equipped with water-cooling means invented by Mr. ANSON W. ALLEN, of Birmingham, Ala. The furnace is of the usual construction, having a gas port 10 and air ports 11. These are separated by an arch 12 of refractory material extending to the point where the best combustion is obtained. Beneath the refractory arch is another composed of metallic

FIG. 4.—WATER-COOLED FURNACE PORT

units 13, these being trapezoidal in cross section and closed at their ends with plugs. The upper plug is apertured to receive a fitting 16, connected with an overflow pipe 17. An additional overflow pipe is provided at 17a, delivering into a trough 17b. Water is supplied separately to each unit through the header 19 and pipe 18. The cooling units are removable without delaying the operation of the furnace. (1,076,540, Oct. 21, 1913.)

Metallic Alloys

Copper-Aluminium.—An improvement in the manufacture of aluminium bronze is suggested in a patent granted to Mr. EDWARD D. GLEASON, of New York City. Poron is used in the preparation of the alloy. Into a fused bath of three parts calcium fluoride and one part fused boracic acid, ingots of aluminium are introduced. When the mass is molten it is stirred and cast into ingots. This mixture is then added in an amount slightly in excess of 10 parts to 90 parts of pure copper melted under a cover of charcoal and black oxide of manganese. The resulting alloy is free from oxide of aluminium, which is said to appear in the ordinary aluminium bronze. The alloy can be made in different degrees of hardness with the same percentage of copper by adding aluminium with more or less boron. (1,076,973, Oct. 28, 1913.)

Lead-Copper-Tin.—Plastic compositions of lead-copper and lead-copper-tin, such as are used for bearing metals, sometimes develop defects due to the lack of affinity of the lead for the copper or copper-tin, resulting in segregation or sweating of the lead. According to an invention of Mr. EDWARD D. GLEASON, such alloys can be made perfectly homogeneous by incorporating a non-metallic derivative of lead, such as the sulphide mineral galena. For example, he may melt 60 lb. copper and add thereto 5 lb. galena, and then gradually add to this mixture 30 lb. lead and 5 lb. tin. (1,077,698-699-700-701, Nov. 4, 1913.)

Malleable Zinc Alloy.—According to an invention of Mr. THOMAS A. BAYLISS, of Warwick, England, a malleable and tough alloy is produced from zinc, aluminium and lead, when the ingredients are present in proportions between the following limits:

Zinc	90.100% and 99.0%
Aluminium	0.001 and 0.1
Lead	0.010 and 0.0

The metal thus obtained is said to be extremely tough and strong, and is malleable and suitable for stamping. (1,074,234, Sept. 30, 1913.)

Hard Copper Alloy.—The following formula gives the ingredients of an alloy patented by Mr. WM. F. NOLAN, of St. Paul, Minn.: Copper, 98.15 per cent; manganese, 1.48 per cent; vanadium 0.25 per cent; aluminium 0.12 per cent. The claims

for the alloy include increased durability, and a degree of hardness which makes the metal useful for cutting tools. After the alloy is mixed, and while yet at dark red heat, it is plunged into oil.

The temper can be removed by heat, but the alloy can be hardened again by heating and immersing in oil. (1,074,285, Sept. 30, 1913.)

Alloy for Metal Tape.—A lead alloy suitable for use as metal tape in winding electrical conductors is patented by Mr. CHARLES P. MCCONNELL, of New York City. The alloy contains lead, antimony and tin in the following proportions:

	Preferred	Maximum	Minimum
Lead	95.00%	96.75%	93.25%
Antimony	4.50	6.00	3.00
Tin	0.50	0.75	0.25

A satisfactory tape made from this metal need be only 0.03 in. thick and can be 1 in. wide, and at the same time have as great or greater strength than tape made entirely of lead 0.006 in. thick and 0.75 in. wide. A material saving of lead is accomplished which is in excess of the cost of the metals added to make the alloy. (1,075,661, Oct. 14, 1913.)

Manufacture of Sodium Alloys.—EDMUND CHARLES RESSITER of Birmingham, England, alloys sodium with other metals in the nascent state. The temperature need never rise above 750 Centigrades during the whole process. To prepare an alloy of sodium and lead, for example, sodium hydrate is fused and reduced with carbon in the form of charcoal. The pot is covered and filled with dry coal gas or other suitable gas. The lead is added in liquid form before or after the reduction takes place, or the mixture of sodium hydrate and carbon is poured into the molten lead. (1,073,523, Sept. 16, 1913.)

Refractories

Refractory Material.—WALTER ARTHUR of Schenectady, N. Y., assigns to the General Electric Co. two processes of manufacturing a refractory material of valuable heat-insulating quality which will withstand temperatures of from 900 to 1100 centigrades or even higher. It has a thermal resistance of from 900 to 1200 thermal ohms per inch cube, the temperature coefficient being very small. It contains mainly silicon, carbon, oxygen, small amounts of metallic impurities and aluminium in one patent, titanium in the other. The charge consists of silica, coke, and either fire clay as an example of aluminium silicate or rutile in the second case; this is subjected to the smothered are of an electric furnace. A volatile product, representing the insulating material, condenses in the form of soft, coherent, somewhat felted masses of grayish or yellowish color; when containing manganese the color is a bluish gray. The apparent density is 0.60 to 0.16, the real density about 2.50. A typical analysis is 45.51% Si, 7.57% C, 40.13% O, 1.07% Ti, .32% Mn, 1.03% Al, 1.08% Fe. (1,072,413 and 1,072,414, Sept. 9, 1913.)

Composite Silicon Carbide Refractory Lining.—Silicon carbide is excellent as a furnace lining for its infusible and refractory nature, but has the disadvantage of high heat conductivity, being a conductor of heat five times better than firebrick. Mr. FRANK J. TONE, of the Carborundum Company, Niagara Falls, has devised a lining in which the working portion exposed to high temperature and requiring stability and strength, is formed of silicon carbide of high refractivity and low thermal resistivity, and backs this layer up with silicon carbide of a form which, although comparatively lacking in strength and refractivity has very high thermal resistivity. For the first named exposed or working portion he uses bricks made of dense silicon carbide, obtained by subjecting a mixture of silicon carbide and carbon to the action of silicon-containing vapors at high temperature. For the second portion he uses porous silicon carbide, obtained by subjecting porous carbon to silicon-containing vapors at a high temperature. This composite silicon-carbide lining may be backed up by ordinary means such as the steel furnace shell or by walls of less refractory brick. (1,078,525, Nov. 11, 1913.)

Sintering

Sintering.—Messrs. QUINCY BENT and EDWIN BARNHART, of Sparrows Point, Md., and JAMES B. LADD, of Ardmore, Pa., patent improvements in the preparation of ore for sintering. The sintering process consists in passing air through the materials, after ignition, thereby causing combustion through the mass to fuse or partly fuse materials in it and to get the mass of fine material into a more or less solid mass suitable for treatment in smelting furnaces. The combustion is supported either by combustible material originally in the fine ore or by carbon purposely added. The new point is that in sintering these fine materials, which must be in a moist state, much better results are secured by separating into small parts the more or less coherent mass of material and by lightly and evenly sprinkling or depositing these small and separate parts so that the entire mass to be treated shall lie loosely and be of uniform density and consistency. (1,078,988, Nov. 18, 1913.)

Iron and Steel

Vanadium in Iron.—Mr. JOHN KIRBY, of Pittsburgh, Pa., incorporates vanadium in muck iron to increase the tensile strength by the following process. He feeds into a heat of muck iron in a puddling furnace about the time the cinder is boiled off and before the iron is ready to ball, a composition including vanadium oxide with a reducing agent and an agent to increase the combustion of the reducing agent, so that the vanadium will be reduced and thoroughly incorporated with the iron. Such a composition may contain 32 parts of vanadium oxide, 8 to 16 aluminium, 8 iron rust, 2 potassium chlorate, 1 black oxide of manganese and 1 barium dioxide. (1,079,129, Nov. 18, 1913.)

Electric Furnaces

Melting Resistor Furnace.—Mr. ALBERT E. GREENE, of Chicago, Ill., patents a resistor furnace for melting. Claim 2 relates to "the combination with a furnace chamber, of electric resistors constituting the primary circuit for an alternating electric current flow, electric resistors arranged in inductive relation to said primary circuit and thereby constituting the secondary circuit, said electric resistors being arranged in proximity to said furnace chamber; whereby heat developed in said resistors is transformed to the charge in said furnace. (1,078,619, Nov. 18, 1913.)

Electrode Holder.—In Fig. 5 is shown a top view of a holder for electrodes used in arc furnaces. A side view is given in Fig. 6. It is designed to provide an easily adjustable support, and one which will make a good electrical contact with the electrode so that hot spots will be avoided. It is the invention of Mr. JOHN ORR, of Schenectady, N. Y., and the patent is assigned to the General Electric Co. The holder con-

sists of an adjustable collar consisting of a number of contact plates joined by links at the adjoining ends, and adapted to make a good contact with the electrode surface when drawn together. A bracket 1 forms a support for the electrode and is attached to the furnace framework. It is longitudinally adjustable by a screw 2 moving in a guide through a block 3. At

FIG. 6.—ELECTRODE HOLDER

the end of the bracket is a contact plate 4, which forms one part of the electrode holder. The other contact plates 5, 6 and 7 are adjustable with respect to the fixed contact plate 4, and preferably consist of some good conductor such as copper. The adjacent ends of the adjustable electrodes are connected by links 8 movably attached to the plates by pins 9. In order to give a good contact with the electrode, the contact

plates have the same configuration, round or square, as the electrode. When the plates 5 and 7 are drawn toward the fixed plate 4 by tightening the screws 11, they exert pressure on the enclosed electrode and provide a good contact. (1,076,054, Oct. 21, 1913.)

Induction Furnace.—LESLIE E. HOWARD, of La Grange, metallurgist of the Simmonds Mfg. Co., describes a new electric melting furnace for bronzes, brass mixtures, white metal, Babbitt, aluminium, iron and steel. The furnace is of the induction type and is characterized by the arrangement of the secondary circuit in form of a fused metal bath of wide cross section, which forms about one-third of the secondary, while two-thirds consist of a solid mass of metal having a very large cross-section relative to the cross-section of the molten portion of the secondary. This construction allows to approach as much as possible open hearth conditions for the molten metal and further to place primary and secondary circuit very close to the magnetic field with the resulting advantage of reducing magnetic leakage. The patent is illustrated. (1,076,887, Oct. 28, 1913.)

Electrolytic Furnaces

Electrolytic Furnace.—DAVID J. HAUSS designs an electric furnace adapted to produce metallic alloys or chemicals or compounds with separate regulation of the temperature at the anode and cathode. It also contains a separate chamber in

FIG. 5.—ELECTRODE HOLDER

sists of an adjustable collar consisting of a number of contact plates joined by links at the adjoining ends, and adapted to make a good contact with the electrode surface when drawn together. A bracket 1 forms a support for the electrode and is attached to the furnace framework. It is longitudinally adjustable by a screw 2 moving in a guide through a block 3. At

FIG. 7.—ELECTROLYTIC FURNACE

which the product accumulates and is preserved from alteration. The main feature of the patent is the combined application of alternating and direct current. Fig. 7 shows the electrodes E and F (the former one installed in the special chamber) connected to a source of direct current, while the electrodes H and I supply the alternating current for heating.

purposes. For the production of alloys the electrode F may be subdivided into two connected in parallel, one being carbon, and the other the alloying metal, a rheostat regulating the proper distribution of the current (1,060,839, May 6, 1913).

Metallic Magnesium.—For the production of metallic magnesium Messrs. ROGER WILLIAM WALLACE and EUGENE WASSMER, of London, England, electrolyze a fused mixture of magnesium chloride and magnesium sulphide in a vessel acting as one electrode with another electrode in the center. One of the advantages is that the nascent chlorine combines with the sulphide so as to form sulphur chloride which does not attack the vessel and electrode. The voltage is 8 to 10. The process is carried out in a closed vessel with a nitrogen atmosphere. (1,079,079, Nov. 18, 1913.)

Electrolytic Apparatus

Diaphragm.—A new combination of materials for an electrolytic diaphragm has been patented by Mr. HERMAN A. WAGNER, of New York City. It consists of a plate molded of a substance such as manganese dioxide, in which has been incorporated mercury and palladium black. The plate is used between porous walls of a substance such as burnt clay. In making the diaphragm, the manganese dioxide is powdered, mixed with mercuric chloride, and treated with an alkaline solution of formic aldehyde to reduce the mercury salt to metal, which is thus finely disseminated through the mass. Palladium black can then be added, and the whole molded and pressed into any desired shape. (1,077,444, Nov. 4, 1913.)

Electrode.—Metallic tungsten is insoluble in ordinary acid or neutral solutions, and can be used as a cathode in such solutions; but it is not useful as an anode because it does not readily allow the current to pass. Mr. ROYALE H. STEVENS, of Salt Lake City, Utah, has discovered that tungsten can be formed into a useful anode material by means of a very thin plating of a metal of the gold group, such as platinum, iridium, ruthenium or gold. The combination gives electrodes that are non-oxidizable and refractory, especially when used in electrolytic work where the current liberates chemically active gases at the anode. The same effect can be obtained by alloying the precious metal with the tungsten, but the plating is preferable as requiring less of the expensive metals. The plating can be accomplished with a current density of 0.05 ampere per square decimeter of the area to be plated. The electrolyte consists of 5 parts of platinum or iridium chloride, 250 parts of disodium phosphate, 50 parts ammonium phosphate, all in 1000 parts water. The solution is boiled until all free ammonia is expelled. (1,077,894-920, Nov. 4, 1913.)

Oxygen and Hydrogen.—In the electrolytic cell of RENE MORITZ, of Wasquehal, France, for the production of oxygen and hydrogen from water, the chief features are details of design by which the two gases produced are carried away to separate containers through independent and isolated ducts and any leakage from one to the other is prevented so as to insure high purity of the gases. Each electrode is bipolar, hydrogen being evolved on one side and oxygen on the other. Means for circulation of the electrolyte are provided. (13,643, Nov. 11, 1913.)

Mold for Electrotyping Processes.—In order to produce a good and lasting mold for silver plating in cyanide, ARTHUR J. TIZLEY brings strips of softened celluloid of required dimensions into intimate contact with the design to be reproduced. The celluloid mold is preferably made up of a plurality of thin sheets, and wire mesh is embedded into the celluloid as a reinforcing element. (1,063,740, June 3, 1913.)

Electric Gas Reactions

Ozonizer.—NEVIL MONROE HOPKINS, of Washington, assigns to the Torpezone Co. of New York the construction of a high-voltage ozonizer. It consists of an inner metal cylinder as one electrode which is filled with a loose permeable mass of copper foil or shavings, an annular passage for the air to be treated, a glass cylinder as dielectric, bearing a heavy metal coating as the other electrode and radiators connected to this

electrode for cooling purposes. The whole apparatus is enclosed in a strong outer glass tube which is perforated in one place for the introduction of a binding-post. Properly constructed caps close the two ends and provide for the in- and outlet of the cooling air and heated air. (1,062,974, May 27, 1913.)

Batteries

Lelanche Cell.—For use as depolarizer in Lelanche cells, Mr. MORDECHAI L. KAPLAN recommends the use of dihydrated manganese peroxide, $MnO_2 \cdot 2H_2O$, produced by treating manganese carbonate with a highly diluted potassium permanganate solution at the boiling temperature of water

This dihydrated manganese peroxide consists of a fine, comparatively dense powder of a grayish blue color. Cells made up with it "show 1.8 volt and are superior with respect to yields and recuperative powers." (1,078,788, Nov. 18, 1913.)

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver.

Charcoal as a Precipitant of Gold in Cyanide Solutions.

—A study of the causes of precipitation of gold from cyanide solutions by means of charcoal is presented in a paper by Mr. MORRIS GREEN, in *Bulletin* No. 109, Inst. Min. & Met. (London). The author considers three possible explanations of the precipitating effect of charcoal: (1) A chemical action in which the carbon participates; (2) a reaction due to osmotic pressure; (3) a reaction due to occluded gases. The results of investigations suggest that the first two assumptions are fallacies, and that precipitation is due to the latter cause.

On the general effect of charcoal, the author presents experiments in which he added freshly ignited charcoal to different portions of the same gold-bearing cyanide solution and agitated the mixtures for varying periods. After agitation for 3, 6, 9, 12, 15 and 18 hours, the various solutions were practically identical, as also were the amounts of gold carried by the charcoal. It is concluded that either the solution is incapable of dissolving the precipitated gold, or that precipitation and dissolution proceeded at the same rates. The charcoal will not precipitate unlimited quantities of gold. Gold which had been precipitated by charcoal was not readily dissolved by fresh cyanide solutions.

The effect of different forms of charcoal was determined. The table shows the percentages of gold precipitated by equal weights of different forms of charcoal, acting under similar conditions on equal quantities of the same gold-bearing cyanide solution.

Precipitating Agent

Precipitating Agent	Per cent gold precipitated
Freshly ignited wood charcoal.	90.3
Wood charcoal exposed in lumps for about 6 mos.	50.0
The above charcoal reheated to incipient redness	84.2
Sugar charcoal (by heating in closed retort)	62.1
Sugar charcoal (by burning in contact with air)	5.0
Sugar charcoal (by H_2SO_4 and washing out acid)	0.0

The effect of the presence of charcoal in a cyanide solution during the dissolution of metallic gold was to precipitate some of the gold, and establish a condition of equilibrium between precipitated and dissolved metal. This equilibrium was not changed after agitation for a number of hours.

All of the foregoing results establish, in the opinion of the author, the fact that carbon *per se* does not participate in the reaction. He further shows that graphite not only does not precipitate gold from cyanide solutions, but aids solution by the formation of an electric couple where gold and graphite meet.

A number of experiments were performed to test the possi-

bility or reaction due to osmotic pressure, but with negative results.

In testing the action of occluded gases, it was found that the removal of the loosely-held gases was not sufficient to destroy the precipitating effect of the charcoal; but that when charcoal was subjected to the action of a powerful vacuum, with the addition of heat, its precipitating effect was decidedly diminished.

Nature of Charcoal

	Per cent gold precipitated
(1) Charcoal exposed to air for about two weeks after manufacture	93.3
(2) The same charcoal (1) heated and exhausted of gases	17.0
(3) Charcoal exposed to air for about one year....	41.2
(4) The same charcoal (3) heated and exhausted of gases	14.8

"It appears, therefore, that the power of charcoal as a precipitant of gold from aurocyanide solution is due to occluded gases." Carbon monoxide and hydrogen were found in the exhausted gases; but since hydrogen was found in quantities too small to account for the observed effects, carbon monoxide is considered to be the active reagent.

Use of Lime in Cyaniding.—The almost universal adoption in cyanide practice of crushing ore in cyanide solution instead of water has introduced new metallurgical problems, one of which is the best method of adding lime to the ore. Mr. A. M. MERTON discusses the general use of lime in cyaniding in *Mining Science*, September, 1913. He makes the rational criticism that few mill designers make adequate provision for handling lime in the mill or for the manner of its addition to the ore. The result is the ineffective use of an expensive reagent.

The functions of lime in cyaniding are classified thus:

- (1) Neutralizes acids formed by the oxidation of sulphides, etc.
- (2) Breaks up metallic salts, forming innocuous hydrates.
- (3) Protects the cyanide solution against carbon dioxide.
- (4) Furnishes alkali to break up silver minerals.
- (5) Protects cyanide solution against latent cyanicides in the ore.

The effect of actions (1) and (2), and to a certain extent (5), becomes apparent during crushing and grinding. The amount of lime to be added for these purposes cannot be determined in the laboratory. The amount of protective alkalinity to be carried must be determined experimentally in the mill. In the case of Mexican silver ores it is common to have the solution at all times a concentrated lime solution.

Lime losses occur as follows:

- (1) Lime-consuming constituents in the ore.
- (2) Lime destroyed by CO_2 in air used in agitating.
- (3) Mechanical loss in solution discharged with tailing.

The author makes a point of the fact that the mere addition of lime to the ore in quantities indicated by laboratory tests will not suffice always to protect the cyanide solution. In the case of an all-sliming treatment, for instance, although the pulp going to the agitators is alkaline, the tube mill grinding classifier sand may be working in acid solution because the lime added at the head of the system is passing from the classifier in the slime, leaving an unprotected sand to be reground. In such circuits it is necessary to see that the solution is properly alkaline at all points, and for this purpose it may be necessary to add the lime at different points instead of at the beginning.

Lime added at the coarse crusher may be only partly effective owing to the impossibility of neutralizing the acid conditions in the larger pieces. If only a part of the lime were added here, sufficient to act on the finely crushed part, and the balance at the secondary grinder where the ore is further comminuted, a saving may be effected and greater efficiency obtained at the same time. Thus in treating an ore requiring 16 lb. lime per ton, the most effective way of adding it was as follows: At the coarse crusher, 3 lb.; at the stamps, 9 lb.;

at the tube mill, 4 lb. In order to get the correct lime conditions for this ore it was necessary that the proper amount be present at each stage of the treatment, and it would have been impossible to get such distribution by adding the entire 16 lb. at the coarse crusher.

The proper addition of lime to cyaniding ores becomes a difficult problem in the case of custom milling, where small lots of different ores are constantly going through the mill. Equal difficulty ensues in the case of ore from one mine in which the acidity fluctuates often. The most satisfactory solution for such problems is to bed the ores, thus making as homogeneous a mixture as possible. An alternative is to keep different classes of ore in separate bins and draw from each to make a uniform mixture.

Attention is called to the varying quality of lime, and to the necessity of buying lime on the basis of its "available" alkaline content. The test used for this purpose is that recommended by the Mines Trials Committee, of South Africa, and is as follows: To 2 gr. of lime crushed to 60-mesh, add 50 gr. of crystallized sugar and 800 c.c. of water. Shake thoroughly and allow to stand for a few hours with occasional shaking. Make up to 1000 c.c., shake and take out 50 or 100 c.c. with a pipette. Titrate with standard oxalic acid using phenolphthalein as an indicator. The standard oxalic acid can be prepared easily by dissolving 22.5 gr. of the crystallized acid in 1000 c.c. of water. In such a solution 1 c.c. = 0.01 gr. CaO.

Standardization of Metallurgical Terms.—Much confusion occurs in technical writing owing to the lack of uniformity in the use of technical terms. With a view to clarifying the situation, the Council of the Chemical, Metallurgical and Mining Society of South Africa has adopted certain standard terms and definitions for use in the society's *Journal*. Some of the terms refer mainly to Rand practice, but most of them will find acceptance in other countries.

1. The following words shall be treated as collective nouns, and therefore used in the singular, unless it shall be necessary to use the plural to make careful distinction: Sand, tailing, fine, black sand, residue, ash, pyrite, concentrate, slag, sulphide, telluride, slime, chloride.

2. The following shall be used in the plural form: Shavings, skimmings, steamings, sweepings, drillings, reserves.

3. Preference should be given to the singular form in: Precipitate, bin, cost, profit, value.

4. The following abbreviations shall not be printed in the plural: Oz., lb., dwts., gr. (grain), c.c., cm., kg., in., gal., m., gm. (gram), mm.

5. As far as possible the following terms (local expressions) shall be avoided: Dirt, mullock or muck (broken ore or waste), kokopan (truck), cheesa stick (firing stick), lasher (shoveler), lashing (shoveling).

6. The following spelling shall be used consistently: By-product, shoot (geological term), chute (opening through which material is guided), by-pass, hydraulicking, siphon, kafir, gram, dike, rise.

7. "Vat" shall be used instead of "tank," "cyaniding" instead of "cyanidation"; "breaking and sorting" instead of "crushing and picking"; (Note: "crushing" equals "stamp-milling" plus "tube-milling"); "ore slime" to distinguish from "gold slime"; "extraction" to refer to metal precipitated from solution; "recovery" to refer to metal won in a form suitable for market.

8. In referring to screening, it should be stated whether the number of holes refers to the square or linear inch, and the diameter of the aperture in decimals of an inch should be given; battery screen should have the gage of wire in decimals of an inch and the percentage of discharge area, mentioned, whenever possible. Temperatures should be expressed in degrees Centigrade, with the equivalent in Fahrenheit in parenthesis. Cyanide and alkali strength shall be expressed in terms of specified reagents, thus: 0.05 per cent KCN; 0.02 per cent NaOH; 0.02 per cent CaO.

9. A ton shall be 2000 lb. A fluid ton shall mean 32 cu. ft.

10. The following scheme illustrates the nomenclature of Rand reduction works:

Fuel.

Pulverized Coal for Metallurgical Furnaces.—It is only within the last 15 years that means for producing initially a fire of high efficiency have advanced to their present state of perfection. In a paper published in the October *Bulletin* of the A. I. M. E., Mr. H. R. BARNHURST presents a case for the use of pulverized coal in metallurgical furnaces. The cement industry was the first in which pulverized coal was extensively used to supply heat for the chemical reactions taking place in the operations, but the production of heat in this way has since extended to other forms of chemical and metallurgical industry. Coal properly ground will burn thoroughly if 85 per cent passes through 200 mesh and 95 per cent through 100 mesh, the measuring screen apertures squaring 1/400 and 1/200 in. respectively. The author has found that such properly ground coal will contain a percentage above 70 capable of passing through a 300-mesh screen, squaring 1/600 in. on the side.

Undoubtedly the proper method of firing pulverized coal is to admit with the fuel the exact quantity of air necessary to the result to be attained, as shown by observation, and to maintain the relationship between the fuel and air quantities as long as conditions desired are being fulfilled. The control of the two factors, fuel and air, is and will be at the root of all success with pulverized or sprayed fuel in metallurgical processes. Pulverized fuel has a great advantage in that the eye of the intelligent operator can tell him whether he is getting the heat to serve his purpose. Also, it is best prepared for the absorption and evolution of heat in the combustion process, and in addition the air is properly prepared for joining in the process.

The author submits the following data on the use of pulverized coal in metallurgical furnaces: In roasting carbonate ores of high sulphur content, the carbon has been driven off and the sulphur reduced within permissible limits by the use of less than 7.5 per cent of fuel upon the weight of the charge. This problem involves the maintenance of a low temperature, about 2100 deg. F., to prevent agglomeration of the fine ore. The same practice obtains in the roasting and nodulizing of ores and flue dust, where the heat is sufficient to cause the material to form nodules but not stick to the furnace.

In open-hearth practice with pulverized coal, steel is being made with this fuel at the rate of from 450 to 500 lb. per net ton of product. This is an average of 45 heats, the fuel and product being carefully weighed. The melts were obtained in less time than with oil, which had been used previously. Following are analyses of slags with each fuel:

	Oil	Coal
SiO ₂ per cent.....	16.0	16.5
FeO, per cent.....	22.0	18.2
MnO	7.4	6.7
P ₂ O ₅	1.7	1.0

The sulphur in the final steel ranged from 0.025 to 0.035 per cent with oil, and 0.035 to 0.04 per cent with coal. The coal contained from 1 to 1.15 per cent sulphur.

In puddling furnaces it is safe to say that iron can be puddled at an average expense of 1200 lb. pulverized fuel per gross ton of muck bar produced; in fact, less than 1000 lb. of coal per gross ton of bars has been shown in practice during periods favorable to high economy.

The average consumption of pulverized fuel in heating furnaces seems to be from 500 to 550 lb. of fuel per gross ton. Busheling furnaces require from 550 to 600 lb.

"To obtain such results, however, the furnaces must be properly proportioned and equipped and in good condition. It must

not be expected that the results obtained by simply squirting coal of greater or less degree of pulverization into a furnace with an unmeasured jet of air, will equal the practice here shown. The figures given are authentic and may be relied upon. Success insists upon dry coal, fine pulverization, proper air supply. Another factor is that the attendants should be interested in the production of high results."

"With the proper predetermined proportioning of the separation, the operation will be elastic or adjustable to a wide range of performance under a very nearly constant percentage of efficiency. This is unattainable in an installation which may or may not be proportioned to the production of high efficiency at any particular duty. For this reason the ease with which pulverized fuel may simply be burned does not assure that the best results are being obtained."

Fuller's Earth

Bulletin No. 71 of the United States Bureau of Mines on the subject of "Fuller's Earth" has just been issued. Charles L. Parsons, the author, in the introduction says:

"The United States produces all of the fuller's earth used for refining petroleum within its borders. On the other hand, most of the fuller's earth used in bleaching edible oils has been imported from England. Recently a few of the refiners of cottonseed oil have begun to utilize domestic fuller's earth, whereas others have been unable to substitute it successfully for English earth in their practice. Many samples of American earth distinctly superior in bleaching power to the English earth have come to the attention of the Bureau of Mines. For these reasons an investigation of the mining, preparation, and use of fuller's earth in this country, especially in its application to edible oils, was conducted in order to ascertain why our own raw material has been deemed inapplicable to our needs.

"During the calendar year 1912, according to figures of the United States Geological Survey, there were imported into the United States 1,070 tons of unground fuller's earth, valued at \$11,619, and 17,130 tons of ground fuller's earth, valued at \$133,718, these values being based on the wholesale market price at the port of origin. The addition of transportation charges, commissions, etc., make the price to the American refiner \$14.50 to \$16 per ton. According to the latest figures compiled by the United States Geological Survey, the United States in 1912 produced 32,715 tons of fuller's earth, valued at \$305,522 or \$9.34 per ton, at the mine. Most of this domestic production was from three plants in Florida and one in southwestern Georgia and was used almost wholly for decolorizing petroleum. A small amount from other localities was used in the refining of edible oils. No figures definitely differentiating fuller's earth from other clays are kept in regard to our exports, but it is certain that several thousand tons of domestic earth was exported to Germany, and it is also true that German refiners of edible oils have used and are using large quantities of American fuller's earth and have a higher appreciation of its merits than our own refiners.

"As a result of the investigations made, the Bureau of Mines believes that the United States has fuller's earth far better suited for refining edible oils than any imported, and that to assure the almost universal use of this earth by American refiners there is required only a careful and intelligent technical control of the preparation of the output and its application to the bleaching of oils."

Copies of this bulletin may be obtained by writing to the Director, Bureau of Mines, Washington, D. C.

The International Oxygen Company announces that the steadily increasing demand for the L. O. C. system of oxygen and hydrogen generating plants has made necessary the removal of their executive offices from 115 Broadway, New York City to their works at Newark, N. J. Additional buildings have been erected to house the executive offices and provide additional manufacturing room for the increased demands made upon the plant. The general sales offices will remain at 115 Broadway, New York, as heretofore.

Dry Concentration and Separation of Minerals.

The Plumb Pneumatic Jig (Editorial Correspondence)

Processes for concentration in the dry way have been experimented with for many years. The goal which has attracted inventors has been the evolution of a machine that would take the place of wet concentrators, particularly in localities where the water supply was insufficient to meet the requirements of wet ore-dressing. Some of the more recent proposals offer the possibility of direct competition with wet methods. The fact that only a few of the dry concentrators invented have ever attained commercial prominence, suggests the probability that the great majority reached only the patent-office stage of development.

Richards¹ classifies pneumatic concentrators under three heads: (1) those in which a continuous air-blast acts on the ore particles and yields graded products; (2) those in which the ore particles are projected through the air by some other force, and are graded according to their momentum; and (3) air jigs.

FIG. 1.—PERSPECTIVE VIEW OF JIG

or those in which a bed of ground ore is subjected to an upward pulsating current of air, resulting in a stratification of the constituent minerals and gangue according to their specific gravities. The pneumatic jig under consideration, which is the invention of Mr. A. M. Plumb, of Denver, Colo., falls naturally within the third class.

A suggestion which led to the development of the Plumb pneumatic jig was obtained from the operation of the Bonson dry concentrating table for iron ores. In this machine an adjustable deck is covered with two sets of riffle cleats or guides, one above the other, running diagonally to each other and at angles with the sides of the deck. When an ore mixture is fed onto the table, to which a reciprocating motion is imparted, a stratification of mineral and gangue occurs; and as the mass progresses over the deck a skimming action is produced by the upper set of cleats, whereby the lighter gangue is diverted in one direction while the concentrate is directed by the lower cleats to another point of discharge.

This process of skimming a stratified pulp by means of a guide or partition extending vertically downward into the mass, is one of the features of the Plumb jig. The method of

securing stratification, however, is comparable to that used in hydraulic jigs, more particularly the Richards pulsator jig. A bed of dry ore on a screen is subjected to upward pulsations of air, without intermittent suction.

The construction and method of operation of this jig are best explained in connection with the accompanying drawings. Fig. 1 shows the jig in perspective, and Fig. 2 in cross-section.

FIG. 2.—CROSS-SECTION OF JIG.

An ore hopper H is provided with a number of feed pipes F, having their lower ends in proximity to the feed plate P. The hopper is adjustable with reference to the feed plate by means of screws S at each end. There is a screen at R on which the ore bed is supported. T is the line of tailing discharge, and C the line for delivery of concentrate. The jig bed J is divided by a vertical extension of the feed plate. There is an air chamber A below the screen, with sides converging to a narrow slot that registers with a slot of similar size in the triangular-shaped air distributor D. The latter is to be connected with a source of compressed air, and a rotary valve is placed in the air line near the jig.

The following dimensions have reference to a jig of commercial size. The base plate is 6 in. by 26 in. The inside dimensions of the jig bed J are 3 in. wide, 24 in. long and 1 in. deep, the last being the height above the screen of the tailing discharge. The concentrate compartment, separated from the main jig bed by the vertical partition, is $\frac{5}{8}$ in. wide, 24 in. long and 0.87 in. deep, the last being the height of the concentrate discharge. The partition between the jig bed and concentrate compartment extends to within $\frac{3}{16}$ in. of the screen. The 24-in. slot for admission of air is $\frac{1}{16}$ in. wide. The screen is 150 mesh, supported between two 20-mesh screens. These dimensions may suggest a toy or model rather than a commercial concentrator, but the jig as outlined shows a capacity ranging from 5 to 10 tons per day, varying with the ore.

No less surprising is the fact that a single form of construction, with no adjustable parts save the feed hopper, should suffice for the treatment of practically all concentrating ores, both with regard to variations in the size of feed and mineral content. A fixed relation has been established between the heights of tailing and concentrate discharges, that will serve for the treatment of a wide range of ores. The conditions governing this fixed form of construction are given below, reference being had to Fig. 3. The figure represents a cross-section of the jig bed, drawn full size. When the jig is in normal operating condition on a given ore, the concentrate and tailing assume relative positions as shown. The tailing plus con-

¹ *Iron Dressing*, Vol. 11, pp. 344-347; and Vol. 111, pp. 1553-1555.

concentrate in the jig bed will balance the concentrate in the other compartment.

Designate the heights of the tailing and concentrate strata in the jig bed as x and y , respectively, and the height of clean concentrate in the other compartment as unity. Assume an ore of the following characteristics:

Sp. gr. of the concentrate, $G = 3$

Sp. gr. of the tailing, $g = 3$

$$3x = 5y, \text{ or } x = \frac{5y}{3} \quad (1)$$

$$5x + 3y = 5 \quad (2)$$

Substituting in (2) the value of x in (1) we have

$$\frac{25y}{3} + 3y = 5, \text{ or } 25y + 9y = 15$$

Hence, $y = \frac{15}{34} = .441$. The general expression for the

$$\text{value } y \text{ is } y = \frac{25 + 9}{G^2 + g^2}$$

Substituting the value of y in (1) we get $x = \frac{2.205}{3} = .735$

Thus the height of $x + y$ for this particular ore will be 1.176, or 117.6 per cent of the height of the concentrate discharge.

For other combinations, for example where $G = 4$ and $g = 2.6$, or $G = 7$ and $g = 5$, the respective values of $x + y$

FIG. 3.—DIAGRAMMATIC CROSS-SECTION OF JIG BED

will be 1.157 and 1.137. The average of these conditions and of others likely to be encountered in concentrating ores will give a value of $x + y = 1.15$; so that if the height $x + y$ in the jig bed be made exactly 1 in., the height of the concentrate discharge will be 0.87 in., and these fixed dimensions will be within 2 per cent, plus or minus, of the figures indicated for any of the various combinations of mineral and gangue.

In operation, the dried ore pulp is fed through the hopper onto the screen. Under the action of the pulsating air current the ore bed becomes "light"; that is, the solid particles are separated from each other by the air which is rising through the mass and gradually expanding to atmospheric pressure. A condition of hindered settling in air is produced, which permits a ready stratification of the constituents of the ore, according to their specific gravities. After a few minutes of operation the bed acquires its normal operating condition for that particular pulp, and the jig bed assumes the condition shown diagrammatically in Fig. 3. The constant addition of further feed causes a displacement which results in the discharge of material over the two weirs, concentrate on one side and tailing on the other. The particles of heavy mineral pass down to the screen, flow under the partition, rise on the opposite side and ultimately pass out of the compartment due to the pulsating air. The tailing particles which are too light to sink into the concentrate stratum are constantly skimmed and discharged over the tailing weir. Thus a single machine can make but two products, concentrate and tailing. The latter may contain lighter minerals which will require a further separation.

Experimental work with the jig has resulted in defining very clearly its limitations as to size of feed. It is not well adapted to work on pulps coarser than 12 mesh, and it will not make a satisfactory separation of minerals ground finer than 150 mesh. Between these two limits, however, the machine gives satisfactory results.

It is a generally accepted principle that the feed for pneumatic concentrators should be more closely sized than for machines using water. The necessity for close sizing for the Plumb jig has not proved as great as might be generally supposed. The results of many tests indicate that three or four sizes between 12 and 150 mesh will be ample for good work, and that considerable latitude can be allowed in the sizing efficiency without materially altering the results of separation.

A convenient grading of the feed is $-12 + 20$, $-20 + 40$ and $-40 + 150$ mesh. Some data of operation are compiled in the following table:

Jig No.	Grade	Air Supply			Capacity, tons, 24 hr.
		Pres- sure, per min.	Pulsa- tions per min.		
1	$-12 + 20$	40	60	700	10
2	$-20 + 40$	10	40	500	8
3	$-40 + 150$	3	15	500	4

Thus three jigs will have a combined capacity of about 1 ton an hour, for which the power requirement will be 8.6 hp.

One of the interesting and valuable features of the jig is its automatic regulation under variations of feed. For any given ore a maximum rate of feed will be determined, dependent on the quantity of mineral to be separated. For all variations in rate of feed between this maximum and zero, the jig is self-regulating and will perform its functions without adjustment. Should the feed cease entirely, the jig would merely stop discharging concentrate and tailing, and would continue to work indefinitely without disturbing the ore bed. When the feed came on again the separation would proceed as usual. An excessively high rate of feed would result in loss of mineral in the tailing.

Equally good regulation is obtained automatically when sudden changes occur in the grade of the feed. Thus if normal feed contains, say, 10 per cent galena, and a change should give 15 per cent, the line between concentrate and tailing (Fig. 3) would rise to a new position and remain there as long as the new feed continued. Should the grade fall to 5 per cent galena, the line between concentrate and tailing would be lowered. In the opinion of a competent authority this is the only jig ever built that perfectly regulates the discharge of concentrate and tailing.

The capacity of the jig will vary with the nature of the ore treated. It is limited by the rate at which concentrate can be discharged. Hence the tonnage capacity will be high on an ore with low mineral content, and *vice versa*. The jig shows its best capacity when treating an ore that yields three tons of tailing per ton of concentrate.

The field of usefulness of the jig is limited by the efficiency of coarse hydraulic jigs on the one hand, and slime concentrators on the other. In extremely favorable cases the jig might be the only concentrator needed to make the best commercial saving; but in most instances it will be used as an accessory to other concentrating and separating devices, such as tables and electrostatic separators. In any event, its work will be confined to that part of the ground or between 12 and 150 mesh in size.

The concentrates produced by this jig are always of high grade, regardless of the grade of the feed; that is, two ores containing 2 per cent and 10 per cent galena, respectively, will yield equally high grade concentrates. After the jig assumes normal operating conditions, as shown in Fig. 3, only heavy mineral particles can reach the screen and pass to the concentrate discharge. The production of high-grade concentrate is a great

advantage to the operator for it enables him to secure the highest market price for his products. In the case of a one-mineral separation, for example, the jig offers an opportunity to increase the quantity of high-grade concentrate, and thus produce a greater net profit, even if the total recovery is not increased. Improvement is shown, also, in the treatment of complex sulphide ores, where the total mineral recovery by wet processes usually is low. In some cases of this kind it has been possible by dry jiggling and electrostatic treatment to separate and recover a part of the minerals at 12 mesh in the form of a clean, high-grade concentrate, leaving a tailing which contains the really complex part of the ore that requires fine grinding and separation on wet tables. Excellent results have been obtained in retreating concentrates from ordinary wet-dressing tables.

A few examples of the work of the jig are given below:

Retreating Products from Wet Concentration.—The two tests below show what can be done by dry jiggling and electrostatic separation in raising the grade of products from table concentration. The original concentrate fairly represents the work done in wet-dressing a lead-zinc-iron ore. But there is a considerable quantity of zinc in the product which is without value; in fact, in the second case the zinc entails a penalty at lead smelters. By separating the original concentrate it is possible to secure this zinc in a merchantable product that will add to the net profit. The method of treatment in both of these tests was to jig the original table concentrate dry, getting a high-grade lead product and a tailing containing the zinc and iron with some lead. This tailing was then separated electrostatically on the Huff machine.

	Weight	Lead	Zinc	Iron

The pneumatic jig is not offered by its sponsors as a cure-all for the ills of concentration. Its apparent usefulness is within

a well defined field, the limitations of which are appreciated. Developments up to date, however, indicate that even within its limited field the pneumatic jig can produce marked and favorable improvement in the present methods of concentrating and separating ores.

The jig is manufactured and sold by the Plum Jig Company, a subsidiary of the American Zinc, Lead and Smelting Company. The latter maintains a custom testing plant and assay laboratory at 1422 Blake Street, Denver, Col., where tests can be made on the Plum jig. Huff electrostatic separator and other concentrating machines. The charges for the work are nominal considering the quality and extent of the tests.

Titanium for Rail Steel

The progress which metallographic methods have made in recent years in the metallurgical art is reflected in a characteristic way in three bulletins issued recently by the Titanium Alloy Manufacturing Company, of Niagara Falls, N. Y., and entitled "Rail Reports" Bulletins No. 1, 2, and 3.

A number of samples of standard and titanium-treated open-hearth rails were sent by several different railroad systems to the laboratories of the Titanium Alloy Manufacturing Company. All the samples were from "A" rails (the top rail from the ingot which usually shows the most excessive segregation): in each case both the standard and titanium-treated rolls had been rolled by the same mill, under the same specifications, with the single exception of the use of 0.10 per cent titanium in the treated steels.

The three bulletins give in detail the results of chemical and physical and microscopic tests of the seven different pairs of samples. A convenient summary of the results of the chemical and physical tests for the seven pairs of samples is given in Bulletin No. 3 in form of a long table from which the following general conclusions are drawn.

First. The tensile tests show on an average much better ductility for the treated rails, especially in the heads, and at the same time a slightly better strength than for the untreated.

Second. The impact tests show an average increase of shock resistance for the treated steel, in the head, web and flange, of about 50% over that for the untreated.

Third. The endurance tests on the White-Souther machine show that the treated rails are much less easily fractured by fatigue or by constantly repeated stresses below the elastic limit than the untreated.

Fourth. The chemical analyses, hardness tests, and Landgraf-Turner endurance tests (in which the stresses exceed the elastic limit), all show a much greater uniformity in the treated samples than in the untreated, indicating that the treated rails are freer from segregation and all its attendant evils.

To sum up all these points, it seems certain that these treated rails, when laid in the track and subjected to the strains and shocks of service, will form a safer line than would the untreated rails and that if excessive segregation is dangerous, the use of ferro-carbon-titanium in open-hearth rail steel is imperative.

Interesting as these physical and chemical tests are yet the beautiful series of sulphur prints and microphotographs given in the three bulletins are probably of even greater interest as they are a distinctly novel feature in a manufacturer's bulletin.

The sulphur prints are made by placing photographic paper on the polished cross sections of rail steels. This paper is moistened with a very weak sulphuric acid solution; and the sulphur in the steel reacts with the acid, forming hydrogen sulphide, which combines with the silver in the paper, producing dark spots thereon. The sulphur print is a rapid and accurate method of determining the quality of steel, and excessive segregation shown by this method indicates a weakness, which the detailed physical tests confirm.

Carbon, phosphorus, and sulphur segregate under similar conditions, so that the degree of segregation of sulphur as

shown by a sulphur print, determines the comparative degrees of segregation of phosphorus and carbon as well. Ample evidence is given in the latter of the three bulletins that this parallelism in the segregation of carbon, phosphorus, and sulphur is indeed a reality.

Cross-sections of the rails were also etched with iodine to reveal segregation and the pictures give, in the whole, the same indications as the sulphur prints.

Finally, a beautiful set of *photomicrographs* is given in each of the three bulletins. These photomicrographs were made of sections taken from the top of the head, center of the head, the web, the bottom of the flange, and the end of the flange. Further microphotographs were made of unetched sections as well as of sections under different etching treatments.

In short, these bulletins are exceedingly interesting. Quite apart from the primary object which is to permit the reader to form an unbiased judgment of the value of titanium treatment of rail steel they permit a very suggestive comparison between the different methods of testing—chemical, physical, and microscopic.

As to the value of titanium-treated steel rails in practice Messrs. Robert W. Hunt & Company are quoted in No. 3 as follows: "Through comparison of wearing results as between the standard open-hearth and the titanium-treated open-hearth rail, the latter in each of a number of instances on four railroad systems has demonstrated its superior wearing qualities. We have yet to find a single exception where the claim just pronounced is not true."

Wet and Dry Bulb Recording Hygrometer

Recording hair hygrometers, giving a single record of the relative humidity, have been in use for a long time. Engineers have appreciated the distinct advantage of having a record of both the dry-bulb temperature and the wet-bulb temperature independently but simultaneously on the same chart. Such an instrument has the added advantage in the ease with which its accuracy can readily be checked with a standard thermometer at all times. The importance of proper conditions of temperature and humidity is being more and more appreciated in its effect on health and human efficiency as also on the effect on many products during process of manufacture.

To meet the growing demand for a wet and dry bulb recording thermometer, the Industrial Instrument Company, Foxboro, Mass., have designed and placed on the market the recording hygrometer illustrated in Fig. 1. It consists of two sensitive bulbs mounted in tandem back of the case as illustrated in

FIG. 1.—WET AND DRY BULB RECORDING HYGROMETER

Fig. 2, the wet bulb being jacketed and kept moist by maintaining water at a constant level in a trough beneath. The pen arms are attached directly to shafts concentric with the helical tube bulbs. The case is mounted on a swivel bracket enabling swinging the instrument at right angles to the wall or support, giving easy access to the inverted glass bottle serving as

water reservoir. It is made in three sizes, viz., 8 in., 10 in. and 12 in., corresponding to the standard sizes of *Barber* recorders and to cover ranges between freezing point and boiling point of water (32 deg. to 212 deg. Fahr., or 0-100 deg. C.).

Fig. 2 illustrates the manner in which the helical tubes acting

FIG. 2.—CONSTRUCTION OF HYGROMETER

as the bulbs are placed in relation to each other and the reservoir A.

These two bulbs extend beyond the case at the rear and the motion is transmitted to the pens through the actuating shafts. The tube marked B is the dry bulb which records the atmospheric temperature. The tube C is the wet bulb, which is covered with a special jacket, leading down into the trough D.

This bulb is always cooler than B due to the evaporation of the water. This evaporation increases or diminishes in proportion to the amount of moisture in the air. Taking the difference between the two records made by the pens and consulting the table sent with the instrument, the relative humidity can be quickly ascertained.

Personal

Mr. G. F. Brindley, who was works manager of the Niagara Electrochemical Company, Niagara Falls, N. Y., from 1896 to 1906, when he left for Japan, subsequently held the position of consulting chemist and engineer to Dr. E. S. Pearson in Mexico, and has recently returned from a prolonged stay in New Brunswick where he was carrying on an investigation of the oil shales of that place. He is at present doing some experimental work at The FitzGerald and Bennie Laboratories, Niagara Falls, N. Y.

Mr. Franz Cazin, of Denver, Col., has been obliged to return to the United States from Mexico, where he was engaged in the design and construction of a large metallurgical plant. Conditions in the southern republic made further work impossible.

Mr. Robert C. Gemmel, general manager for the Utah Copper Company, celebrated his twenty-fifth wedding anniversary on October 17, at which time the operating heads of the Utah Copper Co. presented Mr. and Mrs. Gemmel with a beautiful silver punch service. The bowl is engraved with a panorama of the great Utah copper mine and with scenes depicting the mining and transportation of ore.

Mr. Jay P. Graves, who has been vice-president and general manager of the Granby Consolidated Mining, Smelting & Power Co., of British Columbia, has retired from the active management of the company. He is succeeded by **Mr. F. M. Sylvester**, who has been assistant general manager.

Mr. John Gross, metallurgical engineer of Denver, Col., has finished the construction of a new mill for the London Mines Company, in Gilpin county.

Mr. John T. Jones, of Iron Mountain, Mich., was in Denver recently en route to Utah and Arizona on professional business.

Mr. Robert M. Keeney, of the Bureau of Mines, Pittsburgh, Pa., was married October 22 to Miss Maud Conrad. Mr. and Mrs. Keeney are at home at the Moyer apartments, Oakmont, Pa.

Mr. Thomas M. Kekich has been engaged by the Spassky Copper Mines, Ltd., Siberia. He recently resigned his position as assistant superintendent of the Great Western S. & R. Company, Chicago.

Sir Robert Mond and Sir Alfred Mond were the guests of honor at a dinner tendered by Dr. L. H. Baelkand at the Chemists' Club in New York before their return to England. Dr. Baelkand acted as toastmaster. Sir Robert Mond spoke impressively of the scientific, industrial and commercial problems inherited from his father. Sir Alfred Mond, M. P., spoke very amusingly of the life of a British politician. The other speakers were Dr. W. H. Nichols, Dr. C. F. Chandler and Dr. J. Takamine.

Mr. H. N. Thompson has resigned his position as superintendent of the Tooele smelter of the International Smelting & Refining Co., in Utah. William Wraith, manager of the plant, will assume the duties of Mr. Thompson, and will be assisted by O. M. Ruchs, who has been chief chemist.

Obituary

Ashmead Gray Rodgers for twelve years superintendent of The Carborundum Company's plant at Niagara Falls, died October 23d, 1913, as the result of injuries sustained through an accident on October 3. Mr. Rodgers had a host of friends and acquaintances throughout the mechanical and chemical world and they will sincerely feel the loss of a man who was so pleasing in personality, democratic in his attitude to others, and so capable in his chosen line of work. Mr. Rodgers was a native of Albany, N. Y., having been born there in 1872. Previous to his coming to The Carborundum Company as superintendent he was superintendent of the Eddy Electrical Company, of Hartford, Conn. His funeral services were held Saturday, October 25, from St. Peter's Church at Niagara Falls and was attended by several hundred of the employees of The Carborundum Company, members of the Niagara Club and other friends. Mr. Rodgers was a member of the American Electrochemical Society, the American Chemical Society, Engineers' Society of New York, Chemists' Club, Niagara Club, University Club and Country Club of Niagara Falls and several other scientific and social organizations.

Book Reviews

Metallography. By Cecil Desch.

This book was reviewed in our November number, but the title erroneously given as "Metallurgy."

New Standard Dictionary of the English Language. Edited by Isaac K. Funk; prepared by nearly four hundred specialists. Large quarto (30 x 22 cm.), xxxviii + 2916 pages, nearly 10,000 illustrations, 450,000 definitions. Price, \$21.50, in better bindings, \$27 and \$35. New York and London: Funk & Wagnalls Company.

The appearance of a new complete dictionary, prepared with the great expenditure of money and brains which have been lavished on this new edition of the Standard, is an event worthy of notice in a technical journal. Confining our remarks to the scientific side of the work, and particularly to that which concerns our readers, chemical terms have been supervised by Dr. H. W. Wiley, geology by Director George Otis Smith, of the U. S. Geological Survey, metallurgy and electrochemistry, by Dr. J. W. Richards, mineralogy, by Dr. F. W. Clarke, gems and precious stones by Dr. G. F. Kunz,

electricity by Dr. Samuel Sheldon, engineering and mechanical terms, by C. A. Munn, mining by Dr. J. C. Bayles, former editor of *The Iron Age*. With equally competent experts in charge of other departments of the book, the result is probably as near perfection as it is humanly possible to make such a colossal work. From the printer's and publisher's standpoint, it is a masterpiece of the book-maker's art.

General Metallurgy. By H. O. Hofman, Professor of Metallurgy in the Massachusetts Institute of Technology. Large octavo (15 x 23 cm.), 909 pages, 836 illustrations; price \$6.00 net. New York: McGraw-Hill Book Company, Inc.

This remarkable book is the equivalent of Schnabel's "Allgemeine Hüttenkunde," brought up to date and written in the spirit of modern American metallurgy.

A rather short chapter on the properties of metals is followed by a longer one on alloys; metallic compounds are then described in general terms, with their heats of formation. Over 300 pages are given to "Fuel"; a short 38-page chapter to refractory materials, and 124 pages to smelting processes in general, including fluxes and slags. Only 8 pages are given to the details of hydrometallurgical processes, and but 20 pages to electrometallurgical methods and apparatus. On the other hand, an imposing chapter of 350 pages covers mechanical operations, such as handling ores, working metals and alloys, pumping and filtering liquids, supplying, heating and drying blast, purification of gases and catching of fume.

There is an extraordinary amount of useful information in this work, rendered doubly valuable by numerous references to the literature, so that the reader is everywhere informed where further information can be obtained. There are also numerous mistakes, such as are perhaps unavoidable in compiling such an enormous work, but which must be corrected in the next edition. The reviewer particularly calls attention to the chapter on "Fuel," in which small calories (cal.) and large calories (Cal.) are frequently confused, and in which flame temperatures are in some cases evaluated on a false principle. These, and rather numerous smaller errors and typographical mistakes, are blemishes on the usefulness of what is otherwise a magnificent work and a credit to American technical literature; assuming these corrected in the next edition, we will then be able to recommend the work to students and practitioners, without reservation, as just the work on general metallurgy that we have for so long desired to have.

J. W. RICHARDS.

Industrial Poisoning, from Fumes, Gases and Poisons of Manufacturing Processes. By Dr. J. Ramboisek, Professor of Factory Hygiene and Chief Health Officer of Bohemia. Translated and edited by Thos. M. Legge, M.D., Medical Inspector of Factories. Octavo (21 x 13½ cm.), 360 pages, 61 illustrations. Price, \$3.50 net. New York: Longmans, Green & Co. London: Edward Arnold.

The author is a medical man, a chemist, and a government official, and has treated the subject in a novel, comprehensive and systematic manner. The translator is a physician, and lecturer on factory hygiene in the University of Manchester, England.

The first part of the book describes briefly the process of manufacture of metals and chemicals, the opportunities for poisoning in each case and the symptoms and effects. Part two deals with industrial poisoning in general, its classification, pathology and treatment. Part three deals with preventive measures in general, and in particular cases. A classified bibliography is given in an appendix. One omission is the peculiar poisoning caused by the dust of vanadium ore and oxide, but this is a rather recent discovery; another is the dangerous effects of osmium oxide vapor. The book is, however, very complete, and so well written as to be really fascinating in its interest.

Every worker or firm manufacturing, handling or using chemicals or metals should get a copy of this book.
